Artificial muscle design based on electroactive polymers

Dmitry Lomovtsev, 2nd year Biomedical Mechanical Engineering student
Department of Mechanical Engineering, Faculty of Engineering, University of Ottawa

Introduction

Problem:
- Need for powered human assistive devices to restore mobility of patients.
- Available actuators are heavy and energy inefficient for mobile systems.

Solution:
- Electroactive polymers (EAP) are a smart material that change shape when subjected to electric fields.
- EAP are light and inexpensive.
- EAP actuators can be designed as artificial muscles.

Objectives

- Examine properties of 3M VHB 4910 EAP.
- Design a proof of concept actuator.
- Test its feasibility to be an actuation solution for human assistive devices.

Theoretical background

- 3M VHB 4910 is a dielectric EAP.
- The compression in response to electric field stress (Maxwell stress) induces EAP expansion perpendicular to the field.

- Lateral expansion of EAP film placed in a rigid frame can be controlled by varying electric field to produce motion.

Design and testing methodology

- A spring-loaded stacked film actuator was designed in SolidWorks.
- EAP films were modeled using Hooke’s elastic equations, relating Maxwell stress, biaxial film strain, and applied voltage.
- A pre-straining mechanism was built and used to apply a 400% biaxial strain to the film.
- EAP disks were constructed using acrylic frames and pre-strained EAP coated with carbon grease electrodes.
- EAP displacement was measured under varying load and electric field conditions.

Results

- Pre-strained EAP film displacement fits exponential model \( d = A e^{Bt} - C \), where \( A \), \( B \), and \( C \) are experimentally determined.
- Model-data correlation is 0.978, suggesting a good fit.
- EAP deformation was fully elastic, even with 400% pre-strain. Films returned to original vertical position when voltage turned off.
- A 0.987N load produced greatest displacement, while higher or lower loads produced smaller displacements.

Conclusions and recommendations

- EAP modeling using Hooke’s linear elastic equations is limited, good exponential model fit supports this conclusion.
- Oghden or Mooney-Rivlin differential models with finite element analysis are recommended for EAP modeling.
- An optimal EAP stress level exists, which produces greatest film strain, and therefore greatest displacement of load.
- No viscoelastic deformation was observed even with 400% biaxial EAP pre-strain. May be promising for long-term reliability.
- Recommend testing many EAP samples using biaxial straining apparatus in a universal testing machine.
- The current design employing 10 EAP films could potentially move a 1kg weight by ~4mm. Adding extra films would increase the weight allowance, but not load displacement.
- The presently low displacement of applied loads limits the potential of this actuator design in biomedical applications.

Acknowledgements

I would like to thank:
- Dr. Marc Doumit, Ph. D., P. Eng., Department of Mechanical Engineering, for project guidance and supporting learning excellence
- Alex Helal, M. A. Sc. candidate, Department of Mechanical Engineering, for enormous support and project assistance
- Jada Watson and Pascale Lafrance. UROP office, for making such projects possible
