Abstract

Seventy-five synthetic powder trioctahedral mica samples (between Mg, Co, Ni, and Fe end members, with different degrees of oxidation, vacancy and Al/Si contents, and including an OH/F substitution series) were studied by room-temperature powder X-ray diffraction. The iron-bearing samples were studied by ^{57}Fe Mössbauer spectroscopy. Subsets of the samples were also characterized by scanning electron microscopy combined with energy dispersive spectroscopy, optical microscopy, X-ray fluorescence spectroscopy, and gas chromatography. Lattice parameters (refined under the 1*M* stacking polytype, space group *C*2/*m*) were determined for all powder samples and iron site populations ($^{[4]}Fe^{3+}$, $^{[6]}Fe^{3+}$, and $^{[6]}Fe^{2+}$) were obtained from Mössbauer spectroscopy.

The geometry of coordination polyhedrons from 170 published single crystal structure refinements of trioctahedral-1*M* mica structures (128 natural, 42 synthetic, space group *C*2/*m*) was analysed in detail. Sixty-five published structural refinements corresponding to other stacking polytypes and space groups ($2M_1$, *C*2/*c* = 46; $2M_2$, *C*2/*c* = 4; 2*O* : *Pnmn* = 2, *Ccmm* = 1; 3*T*, $P3_112$ = 12) were used together with the 170 trioctahedral-1*M* single-crystal refinements and the 75 synthetic powder results to establish the validity of the $b = \sqrt{3}a$ relationship. The latter relation is not imposed by any space-group symmetry, except for stacking polytype 3*T*, and it would follow from octahedral cations that are arranged in an ideal hexagonal pattern.

Fractional atomic coordinates were derived in terms of the atomic positions in a 1*M* unit cell of C2/*m* space-group type for each known homogenous mica polytype. These coordinates ensure that all TOT layers in each stacking polytype structure are the same 1*M*-type TOT layer, and were used via simulated powder diffraction intensities to determine polytypic contents in our synthetic powder samples.

A hierarchical sequence of geometrical models was developed, starting from the usual distortions (octahedral flattening and counter-rotation, tetrahedral rotation) towards additional features as they are shown to be required (geometric meso-octahedral sheet, tetrahedral elongation via apical bond adjustment, tetrahedral basal flattening). A complete geometric crystal chemical model for the unit cell of a geometric homo-octahedral 1*M* structure was developed in terms of a minimal number of empirical parameters (octahedral, tetrahedral, and interlayer bond lengths, flattening angles of octahedral and tetrahedral sheets, and tetrahedral rotation angle).

We examined the extent to which the lattice parameter variations of synthetic powder samples with known chemical compositions, oxidation states, and site populations can be

understood in terms of our geometric crystal chemical models, in comparison with the 128 natural and 42 synthetic 1*M* single-crystals. A key difficulty in testing the models on synthetic powders was to establish appropriate characteristic cation-specific bond lengths, which are shown to vary systematically from bond distances obtained using Shannon's radii.

The relation $(c/a)\cos\beta^* = 1/3$ was found to hold exactly (within experimental error) for all synthetic powders whereas it does not hold in general for synthetic and natural 1*M* single-crystals. The above relation is predicted to hold for geometric homo-octahedral sheets (having equal *M*1 and *M*2 site bond lengths) and not to hold for geometric meso-octahedral sheets (having unequal *M*1 and *M*2 site bond lengths). The counter-rotation of the *M*2 site of 1*M* single-crystals exactly (within experimental error) follows the geometric meso-octahedral sheet model, which, assuming a uniform octahedral sheet height and site-specific *M*1 and *M*2 bond lengths, predicts site-specific flattening angles and a counter-rotation angle for the *M*2 site which is uniquely determined by the bond length difference between the *M*1 and *M*2 sites. A geometric meso-octahedral 2:1 layer silicate was shown to require corrugated tetrahedral sheets composed of bond-distorted tetrahedra. Key geometric meso-octahedral distortions in 1*M* single-crystals were identified and elucidated: i) intra-layer top-bottom displacements within a TOT layer; and ii) a tetrahedral bending angle between the apical bond and the pyramidal base formed by the three basal bonds. Plots of lattice parameter *b* versus average-octahedral-bond-length allowed the following distinction to be made: Unoxidized divalent synthetic solid solution series tend to evolve along constant flattening-angle lines whereas trivalent octahedral cation and vacancy bearing natural single-crystals and synthetic powders follow trends with varying flattening angles. We found that the bond length of a given interlayer cationic species monotonously increases as the tetrahedral rotation angle α decreases in trioctahedral-1*M* single-crystals. An upper limit of tetrahedral rotation of $\alpha = 9.5^\circ$ was demonstrated to occur in trioctahedral-1*M* K-rich micas having an $<AlSi_3>$ sheet, for both synthetic powders and natural single-crystals.

Other attempts at applying geometric crystal chemical models and at identifying structuro-chemical relationships from structural refinement data will benefit from the perspective of our more complete and systematic approach based on pursuing simple geometrical models using 'regular' coordination polyhedrons and characteristic cation-specific bond lengths up to the limit beyond which such models are shown to necessarily breakdown because of unavoidable 'non-regular' polyhedral distortions.

Statement of Originality

This thesis was done under the supervision of Dr. Denis G. Rancourt from the Department of Physics of the University of Ottawa, and further advice was provided by Dr. André E. Lalonde from the Department of Earth Sciences. The following describes the extent of my personal involvement in the various parts of the thesis.

Experimental methods and sample characterization (Chapters 2 and 3)

Samples were synthesized by: Dr. Jean-Louis Robert at the CNRS-Orléans, France; Dr. Rob G. Berman at the Geological Survey of Canada, Ottawa, Canada; and Dr. Guenther Redhammer at the University of Salzburg, Austria. Acquisition of samples was made by my supervisor. Corresponding details of sample synthesis and pre-measurement heat treatment are given in Section 3.2.

I performed all the tasks associated to the detailed powder X-ray diffraction analysis of seventy-five (75) synthetic powder trioctahedral mica samples reported in this thesis: sample preparation and data analysis (Section 2.1), collection of diffractograms for each sample (Appendix A), identification of impurity peaks in the diffractograms (summary in Section 3.3; details in Appendices F to N), determination of stacking polytype contents (Chapter 4 and Section 5.2), and lattice parameter refinements (including error analysis; Section 5.1) .

Accurate ferric and ferrous iron site populations (within ~0.2 % of total Fe) of the fifty-three (53) iron-bearing samples were determined from Mössbauer spectroscopy (Section 2.2) using recent data treatment and spectral analysis methods and software developed in Dr. D.G. Rancourt's laboratory, that includes (Section 2.2): i) analytic methods for removing the spectral distortions associated to the effects of absorber thickness; and ii) a powerful Voigt-based fitting method that allows arbitrary-shape quadrupole splitting distributions for each site.

The room-temperature Mössbauer spectra of the 15 samples shown in Appendix B were collected by my supervisor. In the context of this thesis, I have determined the iron site populations for 13 out of the 15 samples shown in Appendix B (two samples were ignored due to significant magnetite impurity peaks seen in the Mössbauer spectra). The populations of the remaining samples were retrieved from my M.Sc. thesis and elsewhere in the literature (see Section 3.5). Fitting parameters for the thirteen (13) thin-limit spectra (generated using the above mentioned methodology; see Section 2.2) are tabulated in Appendix O.

The impurity contents of selected samples (Section 3.3) was also ascertained by scanning

electron microscopy (SEM) combined with energy-dispersive spectroscopy (EDS) (Section 2.3), and by optical microscopy (Section 2.4). I assisted two persons for these measurements: Mrs. Pam Hunt at the Geological Survey of Canada for taking the SEM micrographs and EDS X-ray microanalysis spectra that are shown in Appendix C; and Dr. A.E. Lalonde for collecting the photomicrographs that are displayed in Appendix D.

Because of limited sample amounts, only one sample was examined by X-ray fluorescence spectroscopy (Section 2.5) and gas chromatography (Section 2.6). Elemental analyses provided by these two methods are summarized in Section 3.4.

With the assistance of Mr. Ron Hartree at the University of Ottawa, I have developed a calibration requiring only 250 mg of samples for major-element analysis using a wavelength-dispersive X-ray fluorescence spectrometer. I have also determined the precision and accuracy of the calibration for relevant major elements.

Gas chromatography was performed at the G.G. Hatch Isotope Laboratories of the University of Ottawa with the help of Mrs. Wendi Abdi and Mr. Gilles St-Jean. I have developed a procedure to establish the hydrogen contents of small amounts (1-100 mg) of powder (crystallite size = 0.1-20 μm) samples of layer silicate by gas chromatography. Chromatograms taken in the run corresponding to the one sample studied are given in Appendix E.

Main results (Chapters 4 and 5)

Stacking polytype contents. An area of concern is the complexities introduced by the possible presence of a mixture of stacking polytypes in the samples studied. To deal with this problem, I have derived fractional atomic coordinates for each observed homogenous mica polytype ($2M_1$ and $2M_2$, s.g. *C*2/*c*; 2*O*, s.g. *Ccmm*; and 3*T*, s.g. $P3_112$) in terms of the atomic positions in a standard 1*M* mica layer (these calculations are explained in Chapter 4 and given in Appendix U). By treating the various polytypes as different crystalline phases built of the same 1*M* unit in the simulation of a polytypic mixture, one then establishes clear criteria for identification based on the presence or absence of a Bragg peak at a 2θ position corresponding to a given stacking polytype. The polytypic contents of thirty-six (36) powder samples of four different solid solution series, determined as explained above, are presented in Section 5.2. Several workers have established criteria for the identification of mica polytypes by powder X-ray diffraction, but it is here attempted for the first time via a set of fractional atomic coordinates which ensures that the TOT layers of each stacking polytype are the same 1*M*-type TOT layer.

Lattice parameters. I investigated all factors determining the precision and accuracy of lattice parameters (Section 5.1, Appendices V and X): choice of method for evaluation of peak positions, observational and systematic errors on line positions, effect of indexing scheme on refinement results, etc. Lattice parameters refined for the 75 samples are given in Appendix W.

Models, data analysis, data representations, and interpretations (Chapter 6)

Many synthetic mica solid solution series were studied, between Mg, Co, Ni, and Fe end members, with different degrees of oxidation (induced by hydrothermal synthesis conditions or by heat-treatment), vacancy and Al/Si contents, and including an OH/F substitution series. I have examined the extent to which their lattice parameter variations with known chemical compositions, oxidation states, and site populations can be understood in terms of simple geometric crystal chemical models, in comparison with published crystal structure refinements of 170 single-crystal 1*M* samples (128 natural, 42 synthetic). This is the largest suite of synthetic trioctahedral mica samples ever studied in this way.

Relation to M.Sc. thesis. My M.Sc. thesis focussed on the experimental determination of the iron site populations of the nine (9) annite (Fe end-member) samples considered in this thesis, which were synthesized by Drs. R.G. Berman and J.-L. Robert using the C-CH_4 and Ni-NiO buffers at various equilibration temperatures. A structural model for the lateral misfit of tetrahedral and octahedral sheets of 'real' annite was proposed, that gives definite predictions on the ferric and ferrous iron site populations and includes a cation size dependent octahedral flattening, tetrahedral rotation, and the effect of octahedral/tetrahedral sheet differential thermal expansion. The latter model was based on cationic and anionic radii and has been redefined in terms of bond lengths during my Ph.D.

Geometric crystal chemical models. A hierarchical sequence of progressively more realistic geometrical models for octahedrons and tetrahedrons in layer silicates is developed. The geometrical models for geometric homo-, meso-, and hetero-octahedral sheets of layer silicates were derived by Mr. James R. Evans (University of Ottawa); I adapted his results to the geometry of a conventional 1*M* layer. I have generalized the currently available tetrahedral sheet models to allow tetrahedral elongation (or compression) via apical bond adjustment and/or tetrahedral basal flattening. A complete geometric crystal chemical model for the unit-cell of a geometric homo-octahedral 1*M* structure is worked out in terms of a minimal number of empirical parameters

(octahedral, tetrahedral, and interlayer bond lengths, flattening angles of octahedral and tetrahedral sheets, and tetrahedral rotation angle). I have used such simple geometrical models as a guide in the interpretation of the structural properties of the 170 single-crystal 1*M* samples considered (published refinements) and the 75 synthetic powder samples. A key difficulty in testing the predictions of the models on synthetic powder samples was to establish characteristic cation-specific bond lengths appropriate for these structures. The cation-specific bond lengths which were derived are shown to vary systematically from bond distances calculated using Shannon's radii for network silicates and oxides. Bond lengths specific to layer silicates have also been proposed by [Weiss *et al.* 1985, 1992], but I have argued that these are incorrect.

Distortions of real layer silicates. I have shown that the relation $(c/a)\cos\beta^* = 1/3$ holds exactly (within experimental error) for all synthetic powder samples whereas it does not hold in general for synthetic and natural 1*M* single-crystals of *C*2/*m* symmetry. From the models of [Donnay *et al.* 1964a] and [Evans 2001], the above relation is predicted to hold for geometric homo-octahedral sheets (having equal *M*1 and *M*2 site bond lengths) and not to hold for geometric meso-octahedral sheets (having unequal *M*1 and *M*2 site bond lengths), respectively. I have shown that the counter-rotation of the *M*2 sites of 1*M* samples exactly (within experimental error) follows the geometric meso-octahedral sheet model of [Evans 2001], that assumes only octahedral flattening, uniform thickness, and site-specific *M*1 and *M*2 bond lengths. Limits to simple geometrical models are demonstrated by showing that a geometric meso-octahedral 2:1 layer silicate requires corrugated tetrahedral sheets composed of bond-distorted tetrahedra. The following geometric meso-octahedral distortions were noted in 1*M* structures: i) intra-layer top-bottom displacements within a TOT layer; and ii) a tetrahedral bending of the apical bond with respect to the pyramidal base formed by the three basal bonds. I have shown that plots of lattice parameter *b* versus the average octahedral cation-oxygen bond length are particularly instructive and allow the following distinction to be made: unoxidized synthetic solid series tend to evolve along constant flattening angle lines whereas trivalent octahedral cation and vacancy bearing natural single-crystal and synthetic powder samples follow trends with varying flattening angles. I have found that the bond length of a given interlayer cationic species monotonously varies as a function of the tetrahedral rotation angle α. An upper limit of $\alpha = 9.5°$ is demonstrated to occur for K-rich micas having an $<AlSi_3>$ sheet, for both synthetic powders and natural single-crystals.

Original contributions. The following manuscripts, largely based on the results of Chapter 6, are currently planned or in preparation:

Acknowledgements

First and foremost, I thank my supervisor, Dr. Denis G. Rancourt, for his trust and financial support, for collecting the Mössbauer spectra, and for his guidance and encouragements. Dr. Rancourt is rigorous in his thinking; he expects nothing less from his students; that is what makes him so hard, so good. Thank you, Denis, for teaching me how to do science.

I thank Dr. André E. Lalonde for the optical microscopy measurements and his advice provided on numerous occasions.

I thank Drs. J.-L. Robert, R.G. Berman, and G. Redhammer for the syntheses of the samples.

I thank Dr. G. Redhammer for sharing results of structural refinements of synthetic single-crystal samples prior to their publication.

I thank the following technicians for their help: Mr. Ron Hartree (X-ray fluorescence spectroscopy), Mrs. Pam Hunt (scanning electron microscopy combined with energy-dispersive spectroscopy), and Mrs. Wendi Abdi and Mr. Gilles St-Jean (gas chromatography).

I thank fellow graduate student Jim Evans for fully working out the geometrical models of an octahedral sheet, as well as for the numerous enlightening discussions.

I thank all my colleagues and friends who helped me at various at various stages during my Ph.D. studies and in the production of the thesis: Drs. Meizhen Dang, Ken Lagarec, and Amir A.T. Shabani; Pierre-Jean Thibeault, Jean-François Meunier; Serge Lafontaine, Francis Leblanc, Marc Ducharme, Éric Thériault; Micheline Cormier-Guay, Emmanuelle Guay.

Financial support from Ontario Graduate Scholarships in Science and Technology in association with Golder Associates (1999-2000) and Noranda (2000-2001) is gratefully acknowledged.

I will now move to thank the people who contributed to this project in a more personal way. For that part, I will switch to my mother tongue ...

Je remercie ma conjointe, Emmanuelle Guay, pour m'avoir supporté et soutenu au cours des trois dernières années, même à travers mes périodes tourmentées. Ma Belle Emmanuelle, maintenant que tout est fini, je ne peux vraiment pas voir comment j'aurais pu y arriver sans avoir connu la fraîcheur que tu apportes à ma vie. Tu es ma plus précieuse découverte.

Je remercie les parents d'Emmanuelle, André et Micheline, pour leur générosité et leur hospitalité.

Je remercie Annie Thériault et toute sa famille.

Je remercie mes amis, *Les Boys* , pour leur support moral — et financier lors de nos mémorables fins de semaine.

Je remercie ma famille au grand complet, *des deux côtés*.

Je remercie mes parents, Jean-Paul et Pauline, ainsi que mon frère, Bruno, qui sont toujours là pour m'aider et me supporter du mieux qu'ils le peuvent.

Enfin, je dédie cette thèse à la mémoire de mon autre frère, Régis, qui demeurera toujours ma source d'inspiration la plus profonde.

Chapter 1. Introduction

In this chapter, we first give a preliminary background on layer silicates and the crystal chemistry of mica minerals. We then briefly explain the basic crystal chemical notions used in the understanding of the structures of minerals and inorganic solids. The motivation, perspective, and approach entailed in the long term project pursued in our group are next described along with the scope of the thesis. Finally, a section clarifies the nomenclature of a few important terms used throughout the thesis. An overview of the thesis organization is presented at the end of this introductory chapter.

1.1 Background on layer silicates and the crystal chemistry of the micas

Layer silicates — also called sheet silicates or phyllosilicates — are both common rock forming minerals and important clay minerals. All layer silicates can be conceived as constructed from two types of structural units: sheets of corner-linked tetrahedra and sheets of edge-linked octahedrons. Various cations are found within both the tetrahedral and octahedral sites. The tetrahedrons are usually occupied by Si^{4+}, Al^{3+}, and Fe^{3+}, whereas cations which are usually found in the octahedrons include Fe^{2+}, Fe^{3+}, Al^{3+}, Mg^{2+}, and others.

Depending on the arrangement of the tetrahedral and octahedral sheets, phyllosilicates are described according to their layer type and water content (hydrous *vs.* anhydrous). The assemblage formed by linking one tetrahedral sheet and one octahedral sheet is known as a 1:1 [or T:O] layer. A 2:1 [or T:O:T or TOT] layer links two tetrahedral sheets on either sides of an octahedral sheet. According to Chapter 1 of [Bailey 1988a]: "Hydrous phyllosilicate minerals can be classified conveniently on the basis of layer type (1:1, 2:1, or modulated), layer charge (x) per formula unit, and type of interlayer into several major groups. Further subdivision into subgroups is made on the basis of the octahedral sheet type (dioctahedral [if two-thirds of the octahedral sites are occupied by a cation] or trioctahedral [if all octahedral sites are occupied]) and into species by chemical composition or, occasionally, by the geometry of superposition of individual layers and interlayers. Such a classification scheme for non-modulated hydrous phyllosilicates is given in Table 1 [of the quoted reference]. The structures of the major groups of non-modulated hydrous phyllosilicates are shown diagrammatically in Figure 2 [of the quoted reference]." For further details concerning the classification, nomenclature, and structure of hydrous phyllosilicates other than micas, consult [Bailey 1988a].

Mica minerals belong to the 2:1 sheet silicates. Classification of the mica species is done on the basis of ideal end-member compositions such as those listed in Table 1.1. Structural information on mica and other layer silicates at a more technical level can be found in [Brindley & Brown 1984; Bailey 1984, 1988a; Mottana *et al.* 2002]. An up to date account of the nomenclature and stoichiometry of mica species is given in [Rieder *et al.* 1998]. Figure 1.1 shows the basic features of the mica structure.

Micas are divided into three families according to the symmetry of occupancy of the octahedral sheets in the TOT layers [Ďurovič 1994; Nespolo & Ďurovič 2002; Ferraris & Vivaldi 2002]: i) *homo-octahedral* micas have an octahedral sheet of symmetry $H(\overline{3})1m$, where all three octahedral sites *M*1, *M*2, and *M*3 (see Figure 6.1 of Section 6.1 below) are occupied by the same kind of crystallochemical entity (i.e., by the same the kind of ion or by the same statistical average of different kinds of ions including vacancies); ii) *meso-octahedral* micas have an octahedral sheet of symmetry $P(\overline{3})1m$, where two of the octahedral sites are occupied by the same kind of crystallochemical entity and the third by a different one; and iii) *hetero-octahedral* micas have an octahedral sheet of symmetry $P(3)12$, where each of the three octahedral sites is occupied by a different crystallochemical entity. Two types of TOT layers can also be distinguished in micas: 'M1 layers' have the origin of the octahedral sheet in the *M*1 site, whereas 'M2 layers' have the origin of the octahedral sheet in either the *M*2 or the *M*3 site [Nespolo 2001; Nespolo & Ďurovič 2002; Ferraris & Vivaldi 2002].

As stated in Chapter 1 of [Bailey 1984]: "In its simplest terms the crystal structure of a mica consists of negatively charged 2:1 layers that are compensated and bonded by large, positively charged, interlayer cations. [...] Each tetrahedral sheet is of composition T_2O_5 (T = tetrahedral cation), and within each sheet individual tetrahedra are linked with neighbouring tetrahedra by sharing three corners each (the basal oxygens) to form an hexagonal mesh pattern of the sort illustrated in Figure 1a [of the quoted reference]. The fourth tetrahedral corner (the apical oxygen) points in a direction normal to the sheet and at the same time forms part of an immediately adjacent octahedral sheet in which individual octahedra are linked laterally by sharing octahedral edges (Fig. 1b [of the quoted reference]). In a 2:1 layer the upper and lower planes of anions that comprise an octahedral sheet are also the common planes of junction with two oppositely directed tetrahedral sheets, as in Figure 1c [of the quoted reference]. These planes of junction consist of the shared apical oxygens plus unshared OH groups [or F or Cl anions] that lie at the center of each tetrahedral six-fold ring at [approximately] the same *z*-level as the apical oxygens."

In the octahedral sheet, as explained above, each octahedron shares four corners with the

tetrahedral sheet, leaving two corners occupied by OH groups. If the OH groups are on the same edge of an octahedron, the octahedron is said to be a *cis* site (the *cis* sites correspond to the *M*2 and *M*3 sites; see Figure 6.1 of Section 6.1 below). If the OH groups are opposite to one another on the diagonal of an octahedron, the octahedron is said to be a *trans* site (the *trans* sites correspond to the *M*1 sites; see Figure 6.1 of Section 6.1 below).

Because the apical oxygens of the tetrahedral sheets are shared with the octahedral sheets, the size matching of the two sheets is of critical importance in the formation of a stable mica structure. In annite, for example, the ideal end-member stoichiometry (Table 1.1) is never attained due to sheet structural mismatch constraints between the larger $[Fe^{2+}{}_3]$ octahedral and the smaller $<Al^{3+}Si^{4+}{}_3>$ tetrahedral sheet, which require some Fe^{3+} to be present even under highly reducing conditions [Hazen & Wones 1972, 1978; Mercier 1996; Mercier *et al.* 1996, 1999; Redhammer *et al.* 1993]. On the other end, it is a well known fact that in phlogopite (Table 1.1) the $<Al^{3+}Si^{4+}{}_3>$ tetrahedral sheet is larger than the $[Mg^{2+}{}_3]$ octahedral sheet [Radoslovich & Norrish 1962; Wones 1963a; Redhammer *et al.* 1995].

Inter-sheet lateral commensurateness and bond matching are ensured via several structural mechanisms (e.g, bond length altering, octahedral sheet flattening, tetrahedral rotation, tetrahedral sheet corrugation, etc.; see Chapter 6), as well as various oxidation and chemical substitution reactions, including: the oxybiotite or oxyannite reaction, involving loss of structural H

(1.1) $$Fe^{2+} + (OH)^{-} \rightleftarrows Fe^{3+} + O^{2-} + H\uparrow,$$

an Fe vacancy substitution, involving loss of structural Fe

(1.2) $$3\,Fe^{2+} \rightleftarrows 2\,Fe^{3+} + {}^{[6]}\square + Fe\uparrow$$ (where $\square$ indicates a vacancy),

a change in Al/Si ratio, involving an Al/Si substitution

(1.3) $$Fe^{2+} + Si^{4+} + Al\uparrow \rightleftarrows Fe^{3+} + Al^{3+} + Si\uparrow,$$

an Fe^{3+}/Al^{3+} exchange between the octahedral and tetrahedral sheets

(1.4) $$^{[4]}Al^{3+} + {}^{[6]}Fe^{3+} \rightleftarrows {}^{[6]}Al^{3+} + {}^{[4]}Fe^{3+}$$

and Tschermak's substitution

(1.5) $$^{[6]}(Fe^{2+}, Mg^{2+}) + {}^{[4]}Si^{4+} \rightleftharpoons {}^{[6]}Al^{3+} + {}^{[4]}Fe^{3+} \quad .$$

In the above equations and in general, the prefixes $^{[4]}$ and $^{[6]}$ designate tetrahedral and octahedral coordination, respectively.

1.2 Preliminary crystal chemical notions

The basic ideas used in the understanding of the structures of minerals and inorganic solids are that atoms have a specific size and that crystals can be considered as polymerizations of coordination polyhedra. For a recent review of the state-of-the-art of the field dealing with the fundamental crystal chemistry aspects of minerals, consult [Merlino 1997]. The latter reference also includes a separate chapter on the crystallography of mica polytypes [Nespolo *et al.* 1997a].

Currently, there exist two readily available ways for predicting the bond length of a given cation in a specific coordination: tables of ionic radii [Shannon & Prewitt 1969, 1970; Shannon 1976], and an empirical method that calculates bond lengths by means of a few bond-valence parameters [Brown & Altermatt 1975; Brown 1977, 1987]. Both of these methods are based on systematic, statistical analyses of crystal structure data obtained from inorganic solids. More recently, [Weiss *et al.* 1985; 1992] carried out a statistical evaluation of crystal-structure data for several (~100) phyllosilicates, where multiple regressions were used to obtain bond lengths and ionic radii specific to layer silicates. Numerous statistical studies have also been performed in order to establish relationships between lattice parameters and chemical compositions of micas (e.g., see [Bailey 1984; Smoliar-Zviagina 1993; Guidotti *et al.* 1989, 1993; Radoslovich 1962]).

As will be explained in the next section, the main emphasis of this work is to compare predictions made using simple geometrical models to measured crystal chemical properties of micas. In the vast literature published on the crystal chemistry of micas, there are relatively few papers dealing specifically with such an approach (for examples, see [Pauling 1930, 1960; Franzini & Schiaffino 1963; Donnay *et al.* 1964; Drits 1969; Tepikin *et al.* 1969; McCauley & Newnham 1971; Hazen & Wones 1972; Takeda & Morosin 1975; Appelo 1978; Toraya 1981]). Consult Volumes 13 [Bailey 1984] and 46 [Mottana *et al.* 2002] of the Reviews in Mineralogy and Geochemistry published by the Mineralogical Society of America for a series of papers addressing various aspects of mica crystal chemistry (in particular, see: [Brigatti & Guggenheim 2002; Ferraris & Vivaldi 2002; Nespolo & Durovic 2002]).

1.3 Motivation, perspective, approach, and scope

The ultimate goal of the long term project (not achieved in this thesis) pursued in our group is to develop a fundamental crystal chemical understanding of the links between the equilibration conditions (total pressure, temperature, prevailing gas fugacities, ambient chemical potentials, etc.), the crystallographic structures, and the chemical compositions of a broad array of 2:1 layer silicates.

One motivation of this long term project is to develop a single-mineral multi-variable geosensor based on the crystal chemistry of biotite, which is already the basis of a widely used oxygen fugacity gauge in petrology [Eugster & Wones 1965; Speers 1984]. As biotites are very common constituents of igneous and metamorphic rocks, a knowledge of the intricacies explaining their crystal chemistry immediately leads to their use in evaluating rock genesis or re-equilibration conditions. Most of the currently available geothermometers and geobarometers are based on thermodynamic compositional equilibrium between various minerals that coexist in rocks and are not single-mineral sensors.

Of the many ways one can begin to solve such a vast research problem, a straightforward initial step was adopted: to test the limits of a hierarchy of progressively more realistic simple geometrical models in explaining the crystal chemical properties of trioctahedral micas. It is hoped that the resulting crystal chemical understanding will help in uncovering and correctly describing key links between observed mineral properties and synthesis or equilibration conditions.

The thesis itself consists of a detailed study of the structural properties of 75 synthetic trioctahedral mica samples of different chemical compositions (trioctahedral 2:1 solid solution series having divalent and trivalent cationic, vacancy, and anionic substitutions in the octahedral sheets) which were investigated mainly by powder X-ray diffraction and characterized by several complementary methods. A large number of published crystal structure refinements (235 samples) are also considered. The geometry of the coordination polyhedrons of 170 trioctahedral-1*M* mica structures of *C*2/*m* symmetry is analysed in great detail (128 natural, 42 synthetic). Sixty-five (65) structural refinements corresponding to other stacking polytypes and space groups ($2M_1$, *C*2/*c* = 46; $2M_2$, *C*2/*c* = 4; $2O$: *Pnmn* = 2 , *Ccmm* = 1; $3T$, $P3_112$ = 12) are also used in a more limited way (to ascertain the validity of the studied $b = \sqrt{3}a$ relationship). No structural refinements of subgroup symmetries were considered. All this has lead to uncovering and/or establishing certain crystal chemical relationships that will undoubtedly be useful in the long term objectives mentioned above.

1.4 Nomenclature clarification

The official classification of micas into the homo-octahedral, meso-octahedral, or hetero-octahedral family is based on refinements of site-specific octahedral occupancies (mean electron counts), which correspond to differences in scattering powers of the cations populating each of the three octahedral sites (*M*1, *M*2 , and *M*3). On the other hand, [Weiss *et al.* 1992] identified eight possible configurations of the octahedral sheet based on differences between the average cation-anion bond lengths <M1-O>, <M2-O>, and <M3-O> refined in each of the three octahedral sites. According to their categorisation, three types of octahedral sheets are possible [Weiss *et al.* 1992]:

I. <M1-O> = <M2-O> = <M3-O>

II. (a) <M1-O> > <M2-O> = <M3-O>

(b) <M1-O> = <M3-O> > <M2-O> or <M1-O> = <M2-O> > <M3-O>

(c) <M1-O> < <M2-O> = <M3-O>

(d) <M1-O> = <M2-O> < <M3-O> or <M1-O> = <M3-O> < <M2-O>

III. (a) <M1-O> > <M3-O> > <M2-O> or <M1-O> > <M2-O> > <M3-O>

(b) <M3-O> > <M3-O> > <M2-O> or <M2-O> > <M1-O> > <M3-O>

(c) <M3-O> > <M2-O> > <M1-O> or <M2-O> > <M3-O> > <M1-O> .

As noted by [Weiss *et al.* 1992], the above situation is complicated because sometimes, in a given refinement, the average electron densities of two distinct octahedral sites are different but there is no significant difference between the average bond lengths of these two sites, or vice versa (e.g., see also [Brigatti & Guggenheim 2002]).

In this thesis, we use the terms *geometric homo-octahedral*, *geometric meso-octahedral*, and *geometric hetero-octahedral* to refer to each of three octahedral sheet types I , II, and III described by [Weiss *et al.* 1992], respectively. Note that the latter classification is based on the average bond lengths refined in the three distinct octahedral sites, not on the refinements of site-specific octahedral occupancies. When used without the qualifying adjective *geometric*, the terms *homo-octahedral*, *meso-octahedral*, and *hetero-octahedral* strictly refer to the official classification based on the symmetry of occupancy of the octahedral sheets as judged by the refinements of site-specific mean electron counts [Nespolo & Ďurovič 2002].

1.5 Organization of the thesis

After this introduction, we present the experimental methods and data treatment that were used in this thesis (Chapter 2). The next chapter deals with the synthesis, treatment, and characterization of the 75 synthetic powder samples that were studied (Chapter 3). Chapter 4 proposes a method to resolve the different stacking polytypes that may be present in a given mica sample. Chapter 5 first investigates all factors determining the precision and accuracy of lattice parameters obtained via powder X-ray diffraction, and then applies the method explained in Chapter 4 to determine stacking polytype contents in our synthetic powder samples. The core of the thesis is in Chapter 6, where a hierarchical sequence of geometrical models is presented and then tested against measured structural properties of natural and synthetic trioctahedral micas. Chapter 7 presents a discussion of the main findings made in our detailed analysis of trioctahedral mica structures performed using geometric crystal chemical models. Chapter 8 summarizes the main results and conclusions of this thesis.

Species	Composition
annite	$\{K\}[Fe_3^{2+}]\langle AlSi_3\rangle O_{10}(OH)_2$
phlogopite	$\{K\}[Mg_3]\langle AlSi_3\rangle O_{10}(OH)_2$
siderophyllite	$\{K\}[Fe_2^{2+}Al]\langle Al_2Si_2\rangle O_{10}(OH)_2$
eastonite	$\{K\}[Mg_2Al]\langle Al_2Si_2\rangle O_{10}(OH)_2$
tetra-ferri-annite	$\{K\}[Fe_3^{2+}]\langle Fe^{3+}Si_3\rangle O_{10}(OH)_2$
tetra-ferriphlogopite	$\{K\}[Mg_3]\langle Fe^{3+}Si_3\rangle O_{10}(OH)_2$
tainiolite	$\{K\}[Mg_2Li]\langle Si_4\rangle O_{10}F_2$
polythionite	$\{K\}[Li_2Al]\langle Si_4\rangle O_{10}F_2$
trilithionite	$\{K\}[Li_{1.5}Al_{1.5}]\langle AlSi_3\rangle O_{10}F_2$
norrishite	$\{K\}[LiMn_2^{3+}]\langle Si_4\rangle O_{10}F_2$
preiswerkite	$\{Na\}[Mg_2Al]\langle Al_2Si_2\rangle O_{10}(OH)_2$
clintonite	$\{Ca\}[Mg_2Al]\langle Al_3Si\rangle O_{10}(OH)_2$
kinoshitalite	$\{Ba\}[Mg_3]\langle Al_2Si_2\rangle O_{10}(OH)_2$
paragonite	$\{Na\}[Al_2\square]\langle AlSi_3\rangle O_{10}(OH)_2$

Series	Composition
biotite	Trioctahedral micas between, or close to, the annite-phlopite and syderophyllite-eatonite joins; dark micas without Li.
lepidolite	Trioctahedral micas on, or close to, the trilithionite-polythionite join; light micas with substantial Li.

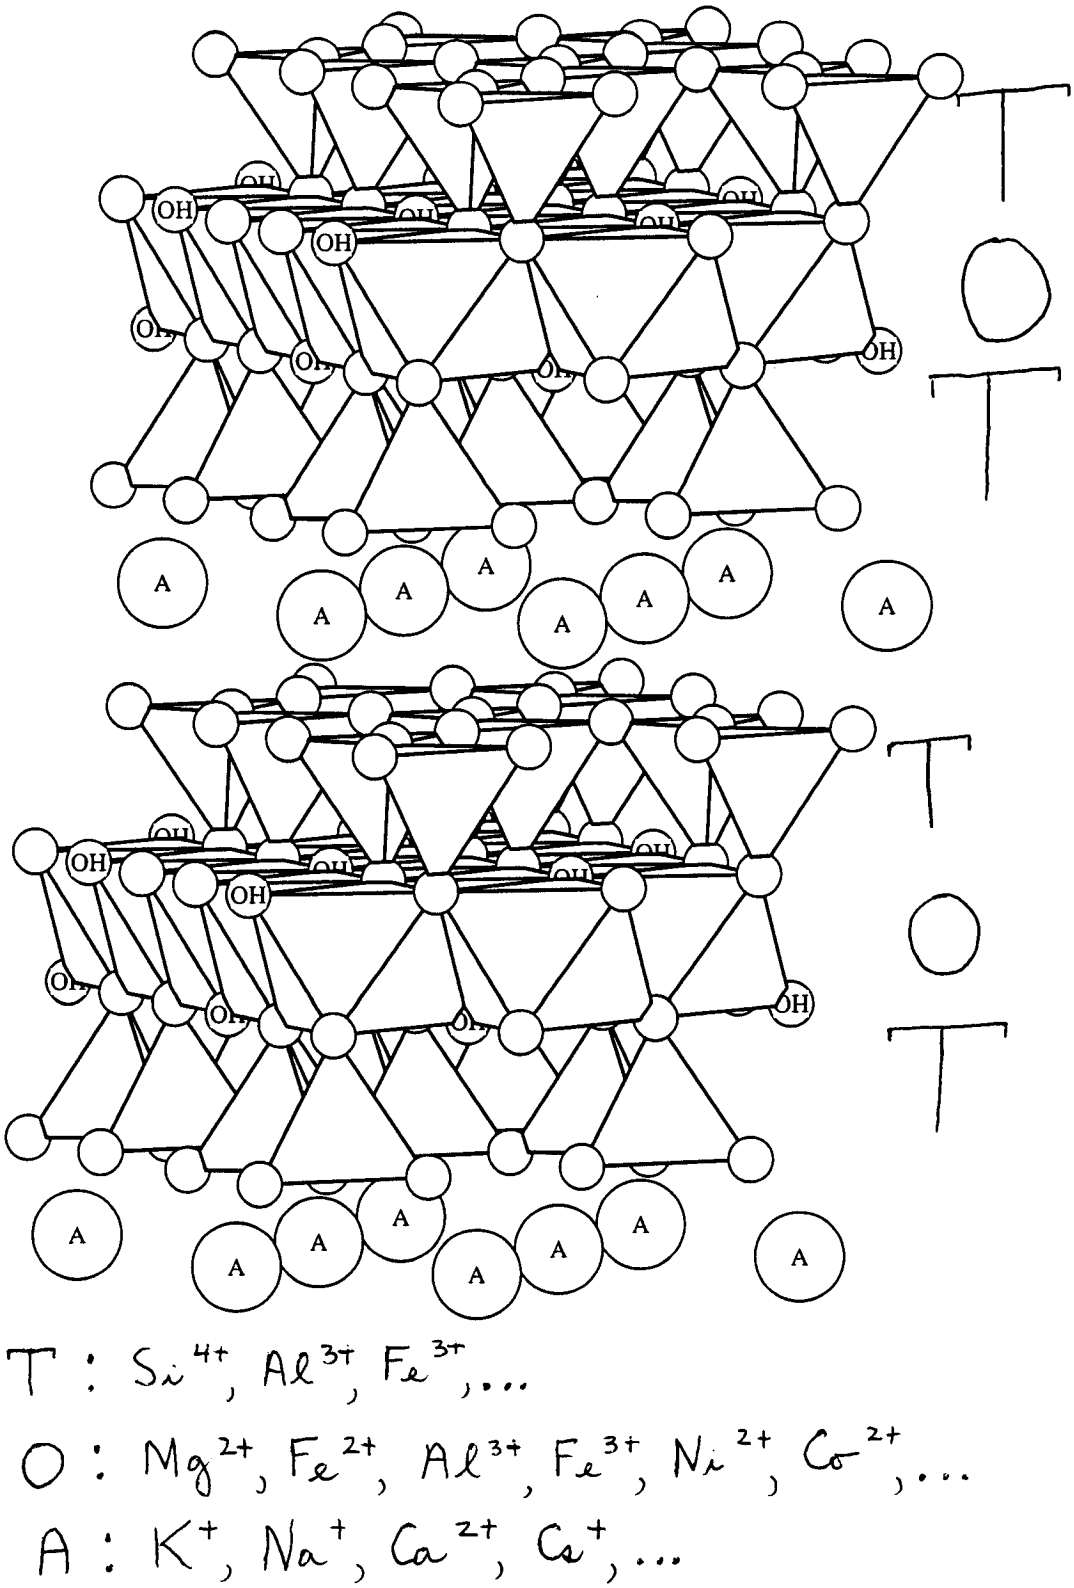

Figure 1.1. Mica structure.

Chapter 2. Experimental Methods and Data Treatment

In this chapter, I describe the experimental methods used in this work. For each method, I give an explanation of: the physical basis of the analytical signal that is measured, the apparatus, the data acquisition, the data treatment, the analytical procedures, and the physical properties that are extracted from the measurements.

2.1 Powder X-ray diffraction

Powder X-ray diffraction (pXRD) is the primary experimental method used in this study. An excellent review of the powder diffraction method is made in [Langford & Louër 1996]. For a complete and up to date reference describing diffraction theory and practice, consult the International Tables for Crystallography [Wilson 1992]. There also exist several monographs devoted to various aspects of X-ray diffraction (XRD): basic theory and experimental methods [James 1948, 1962; Wilson 1949, 1970; Warren 1969], powder diffractometry [Jenkins & Snyder 1996; Klug & Alexander 1974; Wilson 1963; Bish & Post 1989], quantitative X-ray diffractometry [Zevin & Kimmel 1995], Rietveld analysis [Young 1995], and diffraction physics [Cowley 1995; Guinier 1963]. Fundamentals of crystallography can be found in a number of texts, e.g. [Burns & Glazer 1990; Giacovazzo 1992]. For an introduction to solid state physics, I refer the reader to [Kittel 1986; Ashcroft & Mermin 1976].

2.1.1 Apparatus

The pXRD patterns were collected with a Philips X'Pert PW3710 twin-goniometer automated powder diffractometer using Cu-K_α radiation emitted from a 12 mm long line focus sealed X-ray tube. This system employs the Bragg-Brentano parafocusing geometry. A two-dimensional view

of the Bragg-Brentano geometric arrangement is shown in Figure 2.1. A divergent beam of radiation coming from the line of focus (F) of the X-ray tube passes first through a divergent slit (DS) , then through a first set of Soller slits (SS1), through a beam mask (BM), before striking the specimen (S) at an angle θ with respect to the sample plane. The diffracted X-rays leave the specimen at an angle 2θ with respect to the incident beam (and θ with respect to the sample plane), pass through a second set of Soller slits (SS2), through the receiving slit (RS), through the scatter slit (ScS), to the detector. In order to establish the parafocusing condition, the axes of the line of focus of the X-ray tube and of the receiving slit are at an equal distance r_f from the axis of the goniometer.

The receiving slit assembly is coupled to the goniometer and moves around a goniometer circle of radius R, centred about the axis of the goniometer, in order to scan a range of 2θ angles. The source-to-specimen and the specimen-to-receiving-slit distances are both equal to R. For θ-2θ scans, the goniometer rotates the specimen about the same axis as that of the detector, but at half the rotational speed. The surface of the specimen thus remains tangential to the focussing circle r_f .

The system is equipped with two goniometers arranged in a vertical θ-2θ configuration. The goniometers have Soller slits placed in both the primary (incident) and secondary (diffracted) paths of the X-rays. The aperture angle of the Soller slits Δ is equal to 2.3 degrees. Soller slits are made of parallel thin metal foils (at right angle with respect to the direction of the axis of the goniometer) whose spacing and length determine Δ (Δ is equal, in radians, to the spacing of the foils divided by the length of the foils) [Wilson 1963].

The left goniometer has a radius R of 230 mm. It is equipped with a graphite crystal secondary beam monochromator with gas-filled proportional detector, and a non-rotating sample holder. Both the divergent and the receiving slits are adjustable via independently computer-controlled stepper motors.

The right goniometer has a radius R of 173 mm. This side is fitted with a Kevex solid-state detector having sufficient energy resolution to select only the Cu-K_α radiation, and a sample holder that can spin the specimen around an axis perpendicular to the surface of the sample. The divergent slit is an original variable divergent slit system (i.e., mechanically belt-

driven by the θ-axis of the goniometer) that gives a constant specimen irradiation length of 12 mm. The receiving slits are interchangeable and of fixed size.

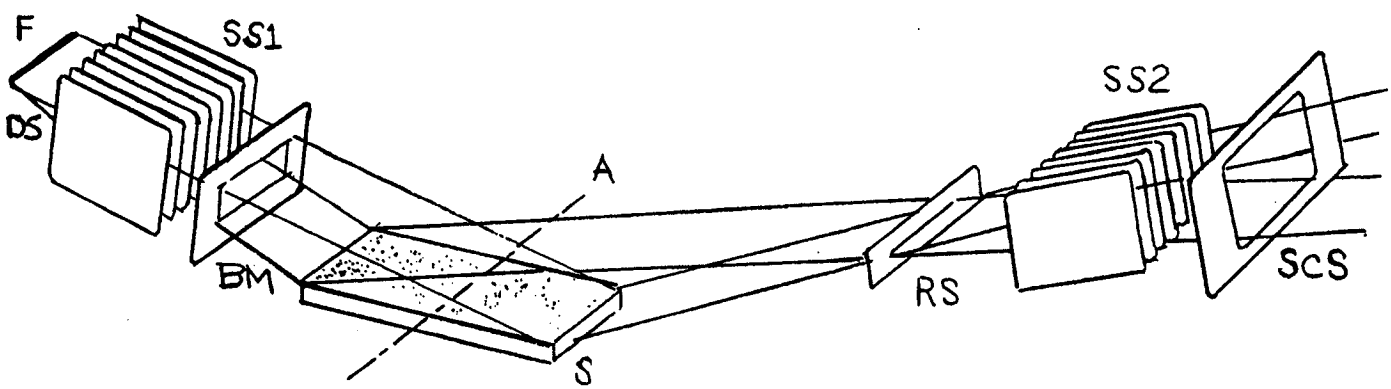

Figure 2.1. The Bragg-Brentano geometric arrangement (detector not shown). Symbols are described in the text.

Inserted in the path of the X-rays between the divergence slit and the specimen, the beam mask determines the axial length of the sample that is illuminated. While smaller beam mask sizes give rise to narrower and better resolved diffraction line profiles, there is a corresponding loss in the intensity diffracted since less sample gets irradiated.

The height of the scatter slit fixes the vertical length of the sample (i.e., the length of the sample perpendicular to the direction of the axis of the goniometer) that is seen by the detector. A scatter slit reduces the background intensity and ensures that the radiation going to the detector is restricted to the X-rays diffracted by the sample.

The function of the divergent slit is to limit the vertical divergence of the X-ray beam. The illuminated length L of the sample is given by [Jenkins & Snyder 1996]:

$$L = \frac{2R\sin\theta\tan(\delta/2)}{(\sin\theta)^2 - (\cos\theta)^2 \cdot (\tan[\theta(\delta/2)])^2} \tag{2.1}$$

where δ is the divergence angle resulting from the aperture of the divergent slit, and R is the goniometer radius. When δ is small ($< 4°$), the second term in the denominator becomes insignificant with respect to the first, and Equation (2.1) reduces to

$$L = \frac{2R\tan(\delta/2)}{\sin\theta} \tag{2.2}$$

The difference between a variable divergence slit and a fixed divergence slit is that the latter produces a fixed divergence angle while the former gives a fixed sample illumination length.

2.1.2 Data collection

Given the small amounts of material available (10-100 mg), samples were mounted as acetone smears on a single-crystal silicon wafer low-background holder. This method of sample

preparation minimizes the specimen-transparency error, provided that the smears are thin enough. A thick smear produces diffraction lines that are shifted towards higher diffractometer angle.

Most diffractograms were collected on the left goniometer in a step-scanning mode from 5 to 80 °2θ, with a step of 0.01 °2θ, and a counting time per step ranging from 3 to 5 seconds. Appendix A presents all the diffractograms collected in this work. Diffractograms are usually referred to as MER*XXX*, where *XXX* is the label number of a given diffractogram.

I also investigated the effects associated to the sizes of the receiving slit, the beam mask, the scatter slit, and the divergent slit. Changing the size of the receiving slit affects both the width and intensity of a given line. In general, as the intensity increases, the resolution of the line decreases, and vice versa. When the beam size is close to the size of the receiving slit, optimum intensity and resolution are obtained. I took a series of measurements on a disk made with a powder of Si crystallites mixed with a resin. In doing so, I established the optimal experimental configuration to consist of a receiving slit height of 0.1 mm and a beam mask width of 10 mm.

The majority of the diffractograms were measured using a variable divergence slit having a 12 mm specimen irradiation length in combination with a 1° scatter slit. Under these conditions, the size of the divergent slit is larger than that of the scatter slit above a certain 2θ angle. Following Equation 2.2, the angle δ subtended by a variable divergent slit is

$$\delta = 2 \cdot \arctan\left(\frac{l \cdot \sin\theta}{2R}\right) \quad , \tag{2.3}$$

where l is the fixed sample illumination length imposed by the variable divergent slit, θ is the Bragg angle (half of the diffraction angle), and R is the radius of the goniometer. Therefore, when the diffraction angle is greater than the value

$$2\theta_o = 2 \cdot \arcsin\left(\frac{2R \tan(\delta_{SeS}/2)}{l}\right), \tag{2.4}$$

where δ_{ScS} is the actual size of the scatter slit in angular units, the diffracted beam is partly blocked by the scatter slit. As a result the length of the sample seen by the detector is no longer constant above $2\theta_o$, but varies as

$$l_{2\theta>2\theta_o} = \frac{2R \cdot \tan[\delta_{ScS}/2]}{\sin\theta}, \tag{2.5}$$

following Eq. 2.4.

With a thin smear and a 1° scatter slit, this implies a constant *effective diffracting volume* up to $2\theta_o = 29.15°$ on the right goniometer ($R = 173$ mm) and up to $2\theta_o = 39.09°$ on the left goniometer ($R = 230$ mm).

2.1.3 Lattice parameter refinement

CELREF is a personal computer (PC) version – initiated on PC by P.C. Burns – of the unit-cell parameters refinement program developed by D.E. Appleman and H.T. Evans for the U.S. Geological Survey [Appleman & Evans 1973]. The reader is referred to the latter publication for a detailed description of the program. The program accepts as input any combination of indexed and unindexed powder diffraction data, along with crystal system, extinction criteria, and approximate lattice parameters. Even though the program is old, it can still run as a DOS-driven application on Windows 95/98/NT systems.

Calculated and observed peak positions are matched according to the following acceptance criterion when the observations are indexed

$$\left|\sqrt{w_i}\left(\theta_i - \text{ARCSIN}\left(0.5 \cdot \lambda \cdot \sqrt{Q_{hkl}}\right)\right)\right| \leq \text{TOL}\ , \tag{2.6}$$

where: θ_i is the observed Bragg angle, w_i is a user-defined weight assigned to the observation, λ

is the X-ray wavelength of the radiation being used, and TOL is the specified tolerance (which can be fixed by the user or determined according to predefined criteria by the program). The value of Q_{hkl} corresponds to the (hkl) indices assigned to the reflection as

$$Q_{hkl} = h^2a^{*2} + k^2b^{*2} + l^2c^{*2} + 2kl\,b^*c^*\cos\alpha^* + 2hl\,a^*c^*\cos\beta^* + 2hk\,a^*b^*\cos\gamma^* \quad , \tag{2.7}$$

where a^*, b^*, c^*, α^*, β^*,and γ^* are the reciprocal cell parameters.

A match is accepted if and only if the difference between the observed and calculated Bragg angle, $\Delta\theta$, is less than the specified tolerance. The program then uses the $\Delta\theta$ values to obtain corrections (shifts) to the reciprocal cell parameters by least-squares analysis. Refinement ends when the reciprocal cell parameter shifts are sufficiently small.

At this point, estimated standard deviations (ESDs) of both the reciprocal and direct cell parameters are computed using the covariance matrix of the least-squares algorithm (for an introduction to the principles of least-squares analysis, consult [Press *et al.* 1996]). All least-squares and error calculations are based on the $\Delta\theta$ values; i.e. the program assumes that the observational error occurs in the determination of θ. In Subsection 5.1.4, I will compare ESDs output by the CELREF program to errors calculated using other methods.

2.1.4 Line-profile refinement and structure factor calculation

XFIT is an interactive and graphical X-ray line profile fitting software program that works under the MS Windows operating system (95/98 and some NT versions), written in the C^{++} programming language. It integrates the familiar pseudo-Voigt and split-Pearson functions, together with a fundamental parameter convolution approach [Cheary & Coelho 1992,1998a, 1998b] to generating line profiles. In the present work, I used the fundamental parameter (FP) approach implemented in XFIT to perform line-profile refinement.

XFIT also incorporates a program, Koalariet, which runs through XFIT using an input

file that consists of readable key words. Koalariet offers the possibility to define parameters, and subsequently refine these parameters in the context of a Rietveld refinement. Koalariet can also execute conventional Rietveld analysis and perform structure factor calculation.

In the FP approach, the line shape (diffraction-line-intensity-profile) is synthesized from the Cu K_α emission profile, the physical variables of the diffractometer, and some specimen-dependent parameters. In addition to the integrated intensities and 2θ positions of the line profiles, both diffractometer- and specimen-dependent parameters may be refined, and constitute the convolution parameters that are used to generate the aberration profiles.

The Cu Kα emission spectrum consists of two major components, $K\alpha_1$ and $K\alpha_2$, which makeup ~99 % of the intensity, and the Kα satellite group of lines in the high-energy tail (lower λ values, i.e. lower-angle side of a diffraction line) which makes up the rest. As explained in [Cheary & Coelho 1992], the Cu spectrum displays a different level of asymmetry in the $K\alpha_1$ and $K\alpha_2$ components; both of these lines are actually two-line structures arising from the fine structure of the $K\alpha_1$ and $K\alpha_2$ transitions. Although in theory each of these lines is also asymmetric, it has been shown that a Lorentzian shape is quite adequate for describing each of these four lines.

In the FP approach, the Cu Kα spectrum emission profile can be represented by a sum of up to five Lorentzian lines, the four Kα lines and the satellite group, and each one of these is expressed as a unit area Lorentzian. Parameters defining the emission profile are stored in a specific file (LAM file) that is used by the program to generate the peaks.

Table 2.1 lists the data contained in the LAM file that I have used to generate the emission profile lines of a peak for line-profile refinements. $E_{o,k}$, $E_{h,k}$, and $E_{A,k}$ are parameter names used to identify the wavelength λ, the full width at half maximum Γ (which is proportional to the lifetime of the excited state giving rise to the emission line), and the relative intensity of the k-th emission line, respectively. The relative areas of the emission lines under a peak are determined by the $E_{A,k}$ values.

The position of a particular k-th emission line of a given peak i, $2\theta_{i,k}$, is determined from the following equations:

$$
\begin{aligned}
2d_{hkl} &= E_{o,r}/\sin\theta_i \\
E_{o,k} &= 2d_{hkl}\sin\theta_k = \left(E_{o,r}/\sin\theta_i\right)\cdot\sin\left(\theta_i + \Delta\theta_{i,k}\right) \\
\Delta 2\theta_{i,k} &= \left(\frac{E_{o,i}}{E_{o,r}} - 1\right)\cdot\left(\frac{360\tan\theta_i}{\pi}\right) \\
2\theta_{i,k} &= 2\theta_r + \Delta 2\theta_{i,k}
\end{aligned}
\qquad (2.9)
$$

where the subscript r refers to the line having the highest $E_{A,k}$ value. The full width parameter at half maximum of an emission line, $H_{i,k}$ (in °2θ), is determined by the relation

$$
H_{i,k} = \left(\lambda_{h,k}/\lambda_{o,r}\right)\cdot\frac{180\tan\theta}{\pi} \qquad . \qquad (2.10)
$$

Emission line	$E_{o,k}$ λ (Å)	$E_{h,k}$ Γ (Å ×10^{-3})	$E_{A,k}$ relative intensity (dimensionless)
satellites	1.534753	3.6854	0.0159
$K\alpha_{1a}$	1.540596	0.437	0.5691
$K\alpha_{1b}$	1.541058	0.6	0.0762
$K\alpha_{2a}$	1.54441	0.52	0.2517
$K\alpha_{2b}$	1.544721	0.62	0.0871

Table 2.1 Relative intensities, wavelengths, and lifetime widths of the emission lines used in line-profile fitting to generate the Cu Kα emission profile. Symbols are described in the text.

The peak (reflection) dependent parameters are its integrated intensity, A_i, and the position, $2\theta_i$, of the emission line having the highest $E_{A,k}$ value. The peak parameter A_i determines the total area under all of the emission lines of a peak. Before scaling by the A_i parameter, the area under all of the emission lines is scaled to unity.

The emission profile, $L(x)$ (where x is the observed angle on the diffractometer) is convoluted with the diffractometer aberration functions, $D_i(2\phi)$, and the total instrumental profile of a peak, $g(x)$, is a convolution of these functions and the emission profile,

$$g(x) = \mathbf{L}*\mathbf{D}_1*\mathbf{D}_2*\mathbf{D}_3*\cdots*\mathbf{D}_n \tag{2.11}$$

where n is the number of instrumental terms included in the convolution. I refer the reader to the original publications [Cheary & Coelho 1992,1998a, 1998b], as well as the documents that come with the program for a full description of the methods and the details concerning the generation of the aberration profiles.

The diffractometer-dependent parameters include: the flat-surface fixed divergence angle (FSFA) in degrees, the flat-surface fixed sample illumination length (FSFL) in mm, the target (source) size (TA) in mm, the specimen tilt (ST) in mm, and the receiving slit width (SW) in mm. The axial divergence aberration function parameters are: the receiving slit length (SL) in mm, the sample length (SAML) in mm, the source length (SOUL) in mm, the primary Soller slit aperture angle (PS) in degrees, and the secondary Soller slit aperture angle (SS) in degrees.

Specimen-dependent factors may also be taken into account through the following aberration parameters: the linear absorption coefficient of the specimen (AB) in cm^{-1}, a Gaussian shape strain (STR) expressed as a percentage, and a Lorentzian shape crystallite size (CS) in Å. The STR parameter is related to the Gaussian full width at half maximum ($FWHM_G$) by

$$\mathrm{FWHM_G} = \frac{4\sqrt{2\ln 2}\cdot\tan\theta\cdot\mathrm{STR}}{100} \quad (\text{in } ^\circ 2\theta), \tag{2.12}$$

whereas the CS parameter is defined in terms of the Lorentzian FWHM ($FWHM_L$) as

$$\text{FWHM}_L = \frac{180}{\pi} \cdot \frac{E_{o,r}}{\text{CS} \cdot \cos\theta} \quad \text{(in °2θ)}, \tag{2.13}$$

where $E_{o,r}$ has been defined above.

The quality of the fit of a given pXRD pattern is judged according to the following profile agreement indicators (used mainly to follow the progress of a given refinement):

$$R_{wp} = \sqrt{\frac{\sum \frac{(Y_{obs} - Y_{cal})^2}{Y_{obs}}}{\sum Y_{obs}}}, \tag{2.14}$$

$$R_{wp}' = \frac{\sum |Y_{obs} - Y_{cal}|}{\sum |Y_{obs} - Bkg|}, \tag{2.15}$$

$$R_{exp} = \sqrt{\frac{N - P}{\sum Y_{obs}}}, \tag{2.16}$$

$$GOF = \frac{R_{wp}}{R_{exp}} = \sqrt{\frac{\sum \frac{(Y_{obs} - Y_{cal})^2}{Y_{obs}}}{N - P}}, \tag{2.17}$$

where: R_{wp} is the R-weighted pattern factor, R_{wp}' is the R-weighted pattern prime factor, R_{exp} is the expected factor, *GOF* is the goodness-of-fit factor, Y_{obs} is the observed intensity at a particular diffractometer angle, Y_{cal} is the calculated intensity at a particular diffractometer angle, N is the total number of observations that make up the pXRD pattern, and P is the number of parameters being fitted in the refinement.

2.2 Mössbauer spectroscopy

Mössbauer spectroscopy is a nuclear spectroscopy that relies on recoilless emission (i.e., without loss of energy due to recoil of the nucleus and without thermal broadening) and subsequent absorption of a γ-ray photon by a nucleus of the sample. [Rancourt 1998] gives an overview of the Mössbauer spectroscopy method. In that article, the author "start[s] from the basics and describe[s] all the physical and chemical concepts that are required to perform correct spectral analysis and interpretation in order to give a complete and up to date treatment so that one may appreciate and use published Mössbauer results. A complete bibliography, including electronic sources [and a number of textbooks and monographs on Mössbauer spectroscopy], is also given" [Rancourt 1998].

Powder absorbers were prepared as described elsewhere [Mercier 1996; Rancourt *et al.* 1994a]. Uniform absorbers are required for thickness-effect corrections, so the following procedure was used. Approximately 20 mg of samples (Table 2.2) was spread evenly and sandwiched between two waxed paper sheets held with clear tape in aluminum holders with 5/16 or 1/2 inch diameter windows. Because of the small particle size of our synthetic samples (see SEM micrographs in Appendix C and [Mercier 1996]), such a procedure ensures that no texture is present in the absorbers [Rancourt *et al.* 1994b].

Transmission ^{57}Fe Mössbauer spectra were collected using a <30 mCi ^{57}Co rhodium matrix single-line thin source with a constant-acceleration drive on a velocity range of ±4 mm/s. This range gives an optimal resolution for the biotite pattern. The same experimental set-up as that described in [Mercier 1996] was used to collect the spectra. Data was acquired on 1024 channels and folded to give a flat background and a zero-velocity position corresponding to the centre shift of metallic α-Fe at RT. The folded raw spectra that I have analysed in this project are presented in Appendix B.

All RT spectra were corrected for thickness effects as described elsewhere [Rancourt 1994; Rancourt *et al.* 1994a, 1994b; Rancourt 1989]. In order to treat thickness effects properly, each spectrum is first fitted with an arbitrary number of Voigt lines to obtain a statistically ideal fit. Intrinsic absorber cross sections (CRS) are then extracted from the Voigt fits and used to

generate thin-limit spectra (TLS). The TLS are fitted using a Voigt-based quadrupole splitting distribution (QSD) method [Rancourt & Ping 1991].

The Rancourt and Ping methodology used here is described in detail elsewhere [Rancourt & Ping 1991; Rancourt *et al.* 1994a, 1994b]. Consult [Rancourt & Ping 1991] for all Mössbauer parameter definitions and a detailed description of the relevant notation. All steps of the analysis procedure were carried out using the Recoil software developed in Dr. D.G. Rancourt's laboratory by Dr. K. Lagarec and now commercialized by ISA Inc. (http//:pages.infinit.net/klagarec/recoil/).

Sample	Weigth (±0.1 mg)	Area (cm^2)

2.3 Scanning electron microscopy combined with energy dispersive spectroscopy

Scanning electron microscopy (SEM) combined with energy dispersive spectroscopy (EDS) permits the observation and characterization of the physical nature and chemical composition of the surfaces of solids on a micrometer or submicrometer scale. The monograph by [Goldstein *et al.* 1992] provides an excellent overview of the SEM and EDS X-ray microanalysis techniques. In their introductory chapter, [Goldstein *et al.* 1992] summarize the basic capabilities of each method as follows: "[In SEM], the signals of greatest interest are the secondary and backscattered electrons, since these vary according to the differences in surface tomography as the electron beam sweeps across the specimen. The secondary-electron emission is confined to a volume near the beam's impact area, permitting images to be obtained at relatively high resolution. [... In EDS X-ray microanalysis], the primary radiation of interest is the characteristic X rays emitted as a result of electron bombardment. The analysis of characteristic X-rays can yield both qualitative identification and quantitative compositional information of a specimen".

In this work, SEM of selected samples prepared as carbon-coated loose powder mounts was performed with a JEOL JSM 6400 system at the Geological Survey of Canada, Ottawa. The EDS X-ray microanalysis was used to look for and identify impurity phases. All SEM micrographs and all EDS X-ray microanalysis spectra are presented in Appendix C.

2.4 Optical microscopy

Optical microscopy is by far the most utilized characterization method in the geosciences for the examination of minerals and rocks. An introductory understanding of the technique is given by R. Telle and G. Petzow in Chapter 5 of [Lifshin 1992]. Optical properties of the micas under the polarizing microscope are summarized by R.E. Wilcox in Chapter 6 of [Bailey 1984], where it is assumed that the reader is acquainted with the theory of optical crystallography which can be found elsewhere [Bloss 1961].

In this thesis, I report on transmission optical microscopy investigations of selected samples (see Chapter 3 and Appendix D) conducted with Dr. André E. Lalonde at the University of Ottawa using either a Meiji ML9400 or a Nikon ECLIPSE E600 POL polarizing microscope. The Nikon microscope was equipped with a digital photo camera, that allowed photomicrographs to be taken. Samples were mounted between two glass plates by immersion in a liquid of known refractive index.

2.5 X-ray fluorescence spectroscopy

X-ray fluorescence (XRF) spectroscopy provides the means for identification and quantification of the chemical composition of a sample by measuring the characteristic X-ray line intensity corresponding to a given chemical element and then relating this intensity to elemental concentration. An introduction to the principles and practice of XRF elemental analysis is given by R. Jenkins in Chapter 9 of [Lifshin 1992] (and references therein). Consult [Ahmedali 1989] for a recent overview of advances in methodology of XRF analysis in the geological sciences.

The XRF experimental method and data treatment that I have carried out in this project are described in [Rancourt *et al.* 2001]: "The XRF elemental analyses were obtained using a Philips PW2400/00 sequential [angle-dispersive] X-ray spectrometer. Because of limited sample amounts, an XRF analysis was performed only for sample [IKO-Ann (see Chapter 3)]. For this purpose, a new calibration was developed that used only 250 mg of sample in preparing fused disks with 4.0750 g of flux material (3.2000 g $Li_2B_4O_7$; 0.8750 g $LiBO_2$). The new calibration was based on a complete suite of international standards. Precision was evaluated by performing several analyses on the same fused disk and was found to be 0.01 wt.% or better (error in the mean) for the relevant major oxides (Fe_2O_3, SiO_2, Al_2O_3, and K_2O). Accuracy was evaluated by measuring five relevant standards, that had not been used in establishing the calibration, and was estimated (average absolute deviations) to be 0.2, 0.3, 0.1, and 0.01 wt.% for Fe_2O_3, SiO_2, Al_2O_3, and K_2O, respectively."

2.6 Gas chromatography

Gas chromatography (GC) of light elements (C, H, N, S) was performed with the CE Instruments model EA-1110 elemental analyser located in the Department of Earth Sciences at the University of Ottawa. With this instrument, the sample is vaporized by combustion and injected into the head of a chromatographic column. Elution is brought about by the flow of an inert gaseous mobile phase and the analyte (sample) signal is measured using thermal conductivity (thermistor) detection. For an introduction to the principles of chromatography, consult [Skoog & Leary 1992].

Quantification was achieved by using time-integrated thermistor signals and run-specific calibrations for C, H, N, and S. In any given run, several standards (typically 10-20) are measured (before, between, and after analyte measurements) and used to construct a calibration line for each element. The names and chemical compositions of the standards that were employed are as follows: BBOT, $C_{0.7253}H_{0.0609}N_{0.0651}S_{0.0744}$; SUL, $C_{0.4184}H_{0.0468}N_{0.1627}S_{0.1862}$; and LCYS, $C_{0.2999}H_{0.0503}N_{0.1166}S_{0.2669}$. These same standard materials are used several times with different sample weights in a given run. Chromatograms collected and analysed in this project are presented in Appendix E, along with the details of the run.

"The calibration curves were found to be linear, within a precision of 0.01 wt.% or better, and were constrained to intersect with the origin in order to avoid systematic errors at the smallest measured values. Detection limit and accuracy were evaluated from the distributions of repeated values for standards and were found to be 0.01 wt.% or better for all elements, including H. All relevant factors that can affect the integrated signals were evaluated, including: sorbed water on the Sn combustion capsule; sorbed water on the sample itself; sorbed water on V_2O_5 combustion agent when used; and the errors in evaluating the integrated signals" [Rancourt *et al.* 2001].

Chapter 3. Sample Synthesis, Treatment, and Characterization

3.1 Hydrothermal synthesis and thermodynamic stability fields

As stated in [Chou & Cygan 1990]: "The pioneering work of [Eugster 1957] on the solid oxygen buffer technique provides a convenient way to control redox states in hydrothermal experiments. Information on the technique's basic theory, the experimental setups as well as its variations, and its applications are contained in papers by [Huebner 1971] and [Chou 1987a]. The basic experimental assembly consists of two nested capsules (Figure 1 [of their paper]) and has often been referred to as the double-capsule technique. The mineral assemblage under study and water are sealed in the inner capsule, constructed of either Pt or one of the Ag-Pd alloys, which are highly permeable to hydrogen. This charge system, together with an oxygen buffer assemblage and water, is in turn sealed in a larger outer capsule, made of either Au or Ag, which are relatively impermeable to hydrogen."

The buffer is usually composed of a metal with its most reduced oxide (e.g., Ni-NiO) or of two oxides with different cation oxidation states (e.g., magnetite, Fe_3O_4, and wüstite, $Fe_{1-x}O$). A buffer mixture resists changes in oxygen fugacity, f_{O_2} (or hydrogen fugacity, f_{H_2}), at constant total pressure, P, and temperature, T. At a fixed P-T condition, therefore, the fugacities of the gas species are fixed by equilibration of the fluid with the solid phases of the buffer, assuming that equilibrium redox states of the buffer system is achieved and maintained during the hydrothermal experiment.

However, the above assumption is not necessarily valid mainly due to the slow kinetics of the buffer reaction and/or the high rate of hydrogen leakage through the buffer container, as indicated by redox measurements of buffer systems made using the hydrogen sensor techniques [Chou & Cygan 1990; Chou & Eugster 1976; Chou 1978, 1987a, 1987b]. Therefore, some of the published data on mineral stability relations in $P-T-f_{O_2}$ or $P-T-f_{H_2}$ space may not be reliable.

Experimental phase relations of the micas are reviewed by D.A. Hewitt and D.R. Wones in Chapter 7 of [Bailey 1984]. Measured thermodynamic stability fields of trioctahedral micas relevant here are those of annite [Chou 1997; Dachs & Benisek 1997; Cygan *et al.* 1996; Dachs 1994; Eugster & Wones 1962], ferriannite [Wones 1963b], phlogopite-biotite solid solution [Wones & Eugster 1965], and Tschermak's substituted biotite [Benisek *et al.* 1996].

3.2 Sample synthesis and treatment

Nominal compositions and synthesis or treatment conditions of samples studied are listed in Table 3.1. In total, nine different sample series having the following structural formulas were investigated:

(3.1) $$\{K^{1+}\}[Co^{2+}_{3-w}\,Mg^{2+}_{w}]<Al^{3+}\,Si^{4+}_{3}>O^{2-}_{10}(OH)^{1-}_{2}$$

(Co-Mg JLR),

(3.2) $$\{K^{1+}\}[Mg^{2+}_{3-w}\,Ni^{2+}_{w}]<Al^{3+}\,Si^{4+}_{3}>O^{2-}_{10}(OH)^{1-}_{2}$$

(Mg-Ni JLR),

(3.3) $$\{K^{1+}\}[Fe^{2+}_{3-x-y-w}\,Mg^{2+}_{w}\,Fe^{3+}_{x}\,Al^{3+}_{y}]<Al^{3+}_{1-y}\,Si^{4+}_{3}\,Fe^{3+}_{y}>O^{2-}_{10+x+y}(OH)^{1-}_{2-x-y}$$

(Fe-Mg JLR),

(3.4) $$\{K^{1+}\}[Fe^{2+}_{3-x-y-w}\,Mg^{2+}_{w}\,Fe^{3+}_{x}\,Al^{3+}_{y}]<Al^{3+}_{1-y}\,Si^{4+}_{3}\,Fe^{3+}_{y}>O^{2-}_{10+x+y}(OH)^{1-}_{2-x-y}$$

(Fe-Mg RGB Al-normal),

(3.5) $$\{K^{1+}\}[Fe^{2+}_{3-x-y-w}\,Mg^{2+}_{w}\,Fe^{3+}_{x}\,Al^{3+}_{y}]<Al^{3+}_{1-y-v}Si^{4+}_{3}Fe^{3+}_{y+v}>O^{2-}_{10+x+y}(OH)^{1-}_{2-x-y}$$

(Fe-Mg RGB Al-poor),

(3.6) $\{K^{1+}\}[Fe^{2+}_{3-w-x}\ Mg^{2+}_{w}\ Fe^{3+}_{x}\ Al^{3+}_{v}]<Al^{3+}_{1+v}Si^{4+}_{3+v}>O^{2-}_{10+x}(OH)^{1-}_{2-x}$

(Fe-Mg RGB Al-rich),

(3.7) $\{K^{1+}\}[Fe^{2+}_{3-x-y-w}\ Ni^{2+}_{w}\ Fe^{3+}_{x}\ Al^{3+}_{y}]<Al^{3+}_{1-y}Si^{4+}_{3}Fe^{3+}_{y}>O^{2-}_{10+x+y}(OH)^{1-}_{2-x-y}$

(Fe-Ni GR),

(3.8) $\{K^{1+}\}[Fe^{2+}_{3-x-y}\ Fe^{3+}_{x}\ Al^{3+}_{y}]<Al^{3+}_{1-y}Si^{4+}_{3}Fe^{3+}_{y}>O^{2-}_{10+x+y}(OH)^{1-}_{2-z-x-y}F_{z}$

(annite-fluoroannite),

(3.9) $\{K^{1+}\}[Fe^{2+}_{3-x-y-3t}\ Fe^{3+}_{x+y+2t}\ \square_{t}]<Al^{3+}_{1-y}Si^{4+}_{3}Fe^{3+}_{y}>O^{2-}_{10+x+y}\ (OH)^{1-}_{2-x-y}$

(annite-oxyannite-ferrioxyannite),

where { }, [ ], and < > represent the interlayer, octahedral, and tetrahedral sites, respectively, and the symbol □ designates an octahedral vacancy.

The determination of the actual values of *w*, *x*, *y*, *u*, *v*, and *t* occurring in the mica phase of each sample, which are induced via various reactions (e.g., structural H loss via the oxybiotite reaction, Al/Fe exchange, Tschermak's substitution, etc.), will be discussed later.

In all syntheses that are studied in this work, no attempt was made to ascertain the attained fugacity values by the hydrogen sensor technique [Chou & Cygan 1990].

Details of the synthesis of the Co-Mg, Mg-Ni, and Fe-Mg JLR series can be found in [Diaz 1999]. These syntheses were performed by Dr. Jean-Louis Robert (JLR) at the CRSCM-CNRS Orléans, France. The starting materials were mechanical mixtures of gels prepared according to the method of [Hamilton & Henderson 1968]. Hydrogen fugacity was buffered by the nickel-nickel oxide (Ni-NiO) assemblage [Eugster & Wones 1962; Huebner & Sato 1970; Chou 1987a] using a variation of the double-capsule method devised by [Eugster 1957]. This variation of the Eugster's method, which was developed at the CRSCM-CNRS Orléans, permits the production of several hundreds of mg of sample during a single hydrothermal experiment.

Syntheses of the Fe-Mg RGB Al-normal, Al-poor, and Al-rich series were performed by Dr. Rob G. Berman (RGB) at the Geological Survey of Canada, Ottawa. Hydrothermal

experiments were conducted in cold-seal hydrothermal apparatus, with pressure vessels made from Haynes Alloy #25 (stellite) and CH_4 or H_2O as the pressure medium. Each pressure vessel was monitored by a 60,000 psi digital strain sensor (within 0.2 % linearity), calibrated to a Heise-Bourdon tube gauge certified by the manufacturer as accurate to within 0.1 % of full scale (0-50,000 psi). Temperatures were controlled and continually monitored by a digital data acquisition and control system made by Sciemetric Inc., Ottawa, Ontario, Canada. Between 100 to 150 mg of each starting stoichiometric mix was sealed in 4 mm O.D. - 3.8 mm I.D. Au capsules with pure H_2O or approximately 10 mg of $KHCO_3$ solution, prepared by adding 10 wt.% $KHCO_3$ to distilled water. The $KHCO_3$ solution was used instead of pure water to enhance reaction rates. All RGB syntheses were equilibrated with the graphite-methane (C-CH_4) buffer [Eugster & Skippen 1967; Chou 1987b].

Samples $Fe_{3.0}Mg_{0.0}$RGB and Fe_{100}RGB-Bi35 were synthesized from stoichiometric mixtures of $KSi_3O_{6.5}$ glass, prepared by the method of [Schairer & Bowen 1955], iron oxalate (FeC_2O_4•2H2O), and γ-Al_2O_3. The remaining samples of the Fe-Mg RGB Al-normal and Al-rich series were synthesized from iron oxalate, MgO, γ-Al_2O_3, K_2CO_3, and cristobalite (SiO_2), mixed to give nominal compositions listed in Table 3.1. MgO, γ-Al_2O_3, and cristobalite were prepared by firing MgO, $Al(OH)_3$, and silicic acid, respectively, at 1000 °C for 20 hours. As for the Fe-Mg RGB Al-poor sample series, they "were synthesized from stoichiometric mixes of $KSi_3O_{6.5}$ glass, prepared by the method of [Schairer & Bowen 1955], iron oxalate (FeC_2O_4•2H_2O), Al_2O_3 glass, and MgO. The latter two oxides were fired at 1000 °C for 20 hours prior to weighing" [Rancourt *et al.* 1994b].

The synthesis of the Fe-Ni GR sample series was done by Dr. Guenther Redhammer (GR) and is desribed in [Redhammer 1998]. These samples were synthesized by standard hydrothermal techniques ("Tuttle-type cold-seal autoclaves, horizontal furnaces, temperature control and regulation by use of Ni/NiCr thermocouples and electronic regulators, online control by a computer" [Redhammer 1998]) from oxide mixtures at redox conditions defined by the Ni-NiO buffer.

The synthesis of annite-fluoroannite sample series is detailed in [Rancourt *et al.* 1996]: "The starting products were mixtures of gels, prepared according to the gelling method of

[Hamilton & Henderson 1968], and dried solid fluorides, mechanically added to the gels in order realize the desired bulk stoichiometries [Table 3.1, present work]. Several fluorides were tested (FeF_2, AlF_3, and KF): all gave reproducible micas and phase assemblages. All experiments were performed in Tuttle-type externally heated pressure vessels at 720 °C, 1 kbar P_{H_2O}, with run durations of one week. The oxygen fugacity was controlled by the double capsule method of [Eugster 1957] using the magnetite-wüstite (MW) assemblage as a solid buffer."

Samples of the annite-oxyannite -ferrioxyannite are described in [Rancourt *et al.* 2001]: "The starting sample was the same synthetic annite sample [labelled as sample IKO-Ann in the present work] that has been characterized in detail by cryogenic and ambient temperature ^{57}Fe Mössbauer spectroscopy, high-field and low-field magnetometry, pXRD, SEM and IR [Rancourt *et al.* 1994a, 1994b]. The original synthesis yielded a large amount of product (10 g) and was not synthesized as previously incorrectly stated in [Rancourt *et al.* 1994a; Mercier 1996] but rather as follows. A hot-seal type autoclave having an internal volume 44 cm^3 was used in which ~10 g of stoichiometric starting gel was sealed in a silver tube and the correct amount of water was added to produce a synthesis pressure of 1 kbar at the synthesis temperature [T_{SYN}] of 600 °C. The relatively large amount of water (~14 cm^3) can take up a considerable amount of dissolved K. In order to ensure K stoichiometry of the annite product, therefore, the water was actually replaced by a 2 M solution of K, as KCl. This gave rise to a certain amount (~10 wt.%) of KCl impurity phase in the dry product that is described below and that does not otherwise affect the synthesis since Cl is not easily incorporated into mica structures [Volfinger *et al.* 1985]. [...]

The oxidized samples were prepared by heating small amounts (typically 20-100 mg) of [sample IKO-Ann] in air at different set temperatures for 5 h [...]. The quench was accomplished by simply pulling the sample and its open-ended quartz tube out of the furnace. The resulting quench rate is not expected to affect the results significantly, given what is known about the kinetics of the relevant reactions."

3.3 Sample characterization and impurity content

In this thesis, samples were characterized primarily by pXRD (powder X-ray diffraction) and Mössbauer spectroscopy. In addition, selected samples were also characterized by optical microscopy and SEM/EDS. In the production of synthetic mica samples, it is important to ascertain whether the run product is a single phase. All diffractograms were searched for the presence of peaks belonging to phases other than mica that are known to occur or that can occur from the bulk starting stoichiometries (Table 3.2).

Preliminary optical examination (i.e., right after synthesis) of the run products of all syntheses by Drs. J.-L. Robert, R.G. Berman, and G. Redhammer indicated almost complete reaction of all starting materials, and that mica was the main phase of all samples. This is confirmed by the characterization of the impurity content of the samples that was performed in this work, which is summarized in Table 3.3.

Samples of the Fe-Mg RGB Al-poor, annite-fluoroannite, and annite-oxyannite-ferrioxyannite series have already been characterized in [Rancourt *et al.* 1994b], [Rancourt *et al.* 1996], and [Rancourt *et al.* 2001], respectively. Slightly different conclusions than those given in the first two papers cited above were reached regarding the impurities that can be detected by pXRD, presumably because those studies used diffractograms of lesser quality.

All reflections that are observed in any given diffractogram of a particular sample can be indexed to belong either to an known impurity phase or to one of the various mica stacking polytypes, except for a few cases noted in Table 3.3. The identification of the impurity reflections detected in the diffractograms was done on the basis of pXRD patterns calculated using published crystal structure refinements retrieved from the crystal structure database that is available interactively on the web site of the Mineralogical Society of America (www.minsocam.org). I used the software programs XFIT (described in Chapter 2) or POWDER CELL Version 2.3 [Krauss & Nolze 1996] to simulate the impurity patterns. In the case of the presence of a mixture of mica stacking polytypes, I have determined the reflections belonging to each stacking polytype using the stacking polytype crystal structure models that are presented in Chapter 4. The stacking polytype content of the samples is discussed in Section 5.3. Results of

the identification of reflections observed for each sample series studied are presented in Appendix F to N, inclusively.

Impurity phase	Composition
kalsilite	KAlSiO4
sanidine	$KAlSi_3O_8$
olivine	$(Fe,Mg,Ni,Co)_2SiO_4$
almandine garnet	$Fe_3Al_2Si_3O_{12}$
hematite	Fe_2O_3
corrundum	Al_2O_3

[1] Sa = sanidine ($KAlSi_3O_8$); Mag = magnetite (Fe_3O_4); Fa = fayalite (Fe_2SiO_4); Cor = corundum (Al_2O_3)
Hem = hematite (Fe_2O_3); Lct = leucite ($KAlSi_2O_6$); Kls = kalsilite ($KAlSiO_4$); Alm = almandine ($Fe_3Al_2Si_3O_{12}$);
Top = topaz ($Al_2[F,OH]_2SiO_4$). A ? sign indicates that only one or two peaks could unambiguously be attributed to this phase.

[2] No quantification was attempted by pXRD.

[3] MBS = Mossbauer spectroscopy; OM = optical microscopy, Raman = Raman spectroscopy; SQUID = SQUID magnetometry.

[4] Expressed as Vol.% visually estimated, except for MBS and SQUID where no quantification was attempted.

[5] See also [Rancourt *et al*. 1994b].

[6] See also [Rancourt *et al*. 1996].

[7] See also [Rancourt *et al*. 2001].

[8] See [Mercier 1996]. In that reference, this sample is denoted as HK-NNO.

[9] This sample was treated with chloroform to remove MBS absorber grease, which apparently removed KCl and produced KO_2.

[10] See [Rancourt *et al*. 2001] for a quantification of the relative amounts of the α-Fe_2O_3 and a-Fe oxide phases w.r.t. the mica phase.

[11] Two small unidentified peaks are seen at 3.52 and 3.50 Angstoms (25.28 and 25.43 $^o2\theta$, respectively) in this sample.

Table 3.3. Continued.

3.4 Elemental analyses of sample IKO-Ann

Results of the elemental analyses of sample IKO-Ann performed in this thesis are reported in [Rancourt *et al.* 2001]: "The XRF results, with accuracies calculated as explained [... in Section 2.5], can be stated as follows, with elemental amounts expressed as weight percentages of assumed oxides: 41.3(2)% Fe_2O_3, 30.2(3)% SiO_2, 8.6(1)% Al_2O_3, 14.55(1)% K_2O, and -2(%) LOI (i.e. gain). The total is consistent with the known KCl impurity and the fact that Cl was not analysed and the known ferric/ferrous ratio of the sample. Of all usual elements, the only significant impurity was one of 1860(80) ppm of Co (0.2% Co), probably arising from an impurity in the starting materials. We expect Co to behave as Fe^{2+} in the annite structure. If we ignore the Co, the relevant elemental ratios and their accuracies can be expressed as: Al/Si = 0.337(5), Fe/Si = 1.03(1), and K/Si = 0.615(6), compared to the ideal values of [...] $\frac{1}{3}$, 1 and $\frac{1}{3}$, respectively. The Al:Si:Fe ratio, therefore, is ideal within experimental error. At worst, there is a small excess of Fe (or Fe + Co), and no evidence for octahedral vacancies. The excess K is understood in terms of the synthesis method, as described [... in Section 3.2], and the excess (calculated as a weight ratio, KCl/annite = 12.3 %) is in quantitative agreement with the amounts of KCl estimated by pXRD, that fall in the range KCl/annite = 6-19 % (Table 2 [of the quoted reference]). These amounts of KCl are also consistent with the large crystal (~10 μm) crystals of KCl that are seen in SEM micrographs that have compositions confirmed by EDS [Mercier 1996].

The GC [gas chromatography] gives an independent evaluation of the total in [... sample IKO-Ann]. The result based on 10 different analyses is 0.33(1) wt.% H (one standard deviation error), in excellent agreement with the NRA result [nuclear reaction analysis result reported in the quoted reference]. [...] No S was detected. A small N signal is near the detection limit. There is also 0.122(1) wt.% C probably substituting for Si in the annite structure."

3.5 Iron site populations from room-temperature Mössbauer spectroscopy

As explained in [Rancourt *et al.* 2001]: "Since accurate Fe-site populations were required in this application [...], it was necessary to perform full absorber thickness corrections. [... I] used the procedure of [Rancourt 1989, 1996] that is implemented in Recoil [to accomplish this task]. This involves generating a synthetic thin-limit spectrum using the raw folded data, that is completely corrected for absorber thickness effects, both spectral shape and relative and absolute intensities. Such corrected spectra are then analysed in the same way as the raw folded spectra, using QSDs and HFDs. The only required user-supplied parameter for this exact correction is the average recoil-less fraction of the absorber material [Rancourt *et al.* 1993]. This recoil-less fraction has been measured to be $f_a = 0.5$ for synthetic annite [Royer 1991; Rancourt *et al.* 1994a], which is the value [... I] have used. It is important to note that the precise value of f_a, where, for example, $f_a = 0.7$ gives the same results within experimental error. [... It] is found that thickness effects cause systematic errors of several percent or more in site populations".

In obtaining site populations from Mössbauer spectroscopy, there is always the possibility that the site-specific or cation-species-specific recoil-less fractions may not be equal in a given sample [Rancourt 1989]. In the present work, equal recoil-less fractions were assumed for all Fe-sites in a given sample. For a complete explanation of the reasons validating that assumption, see [Rancourt *et al.* 2001].

The thin limit (or thickness corrected) spectra of the JLR and RGB samples were fitted with a 1-1-3 model: one tetrahedral Fe^{3+} site having one Gaussian component in its QSD, an octahedral Fe^{3+} site also having one Gaussian component, and an octahedral Fe^{2+} site with three Gaussian components in its QSD. All spectra were thickness corrected such that to each raw spectrum there corresponds a simulated thin-limit spectrum. The fitting parameters of the room-temperature thin-limit spectra of the JLR and RGB samples are given in Appendix O.

Table 3.4 gives the $<Fe^{3+}>$, $[Fe^{3+}]$, and $[Fe^{2+}]$ site populations of all iron-bearing samples. Site populations of Fe-Ni GR, annite-fluoroannite, and annite-oxyannite-ferrioxyannite samples were taken from [Redhammer pers.comm.], [Rancourt *et al.* 1996], and [Rancourt *et al.* 2001], respectively. All these studies employ the same methodology that is used here.

Sample	$<Fe^{3+}>/Fe_{tot}$ (%)	$[Fe^{3+}]/Fe_{tot}$ (%)	$[Fe^{2+}]/Fe_{tot}$ (%)	Fe_{oxide}/Fe_{tot} (%)

Chapter 4. Resolving the Different Stacking Polytypes

The identification and quantification of the individual crystalline phases in a mixture consisting of either various layer silicates or different stacking polytypes of a given mineral is a difficult problem that has been the subject of extensive work (e.g., see [Bailey 1984, 1988b; Reynolds 1985; Plançon 1981; Drits & Tchoubar 1990; Takeda & Ross 1995; Nespolo *et al.* 1997b, 2000; Ďurovič *et al.* 1984; Weiss & Wiewiora 1986]).

In this thesis, the problem of resolving the different mica stacking polytypes was handled in the following manner. Given the current knowledge regarding the occurrences of the various mica polytypes (see Sections 4.1 and 4.2), a set of fractional atomic coordinates was worked out for each common polytype by applying the proper generating (stacking) operations to a conventional 1*M* mica unit cell of space-group type *C*2/*m*. The coordinates that were derived ensure that all TOT layers in each stacking polytype structure are the same 1*M*-type TOT layer. It was then possible to calculate structure factors, simulate pXRD patterns, and establish clear criteria for the proper identification and quantification of the different stacking polytypes.

4.1 Introduction to mica polytypism

A concise introductory description of mica polytypism and its different stacking polytypes is given in [Nespolo 2001]:

> "Polytypism arises from the stacking of the M [TOT] layer along the *c* axis: the geometrical operation relating pairs of layers is a two-fold axis in the interlayer, and adjacent layers result rotated by $n \times 60^{\circ}$ ($0 \le n \le 5$) about c^*. Polytypes in which the position of any layer relative to the others and the transition from it to adjacent ones are the same or equivalent for all layers are termed *homogeneous* [Zvyagin 1988]. Homogeneous polytypes have successive M [TOT] layers rotated always by the same angle, apart from the sign, and correspond to the so-called "simple polymorphs" in [Smith & Yoder 1956]. By using [Ramsdell 1947] notation, homogeneous polytypes are identified as 1*M*, $2M_1$, 3*T*, $2M_2$, 2*O*, and 6*H* [...]. The remaining polytypes are termed *inhomogeneous* and correspond to the "complex polymorphs" in [Smith & Yoder 1956].

Mica polytypes are then suitably classified into three kinds, depending on the geometrical equivalence of layer pairs [Ďurovič *et al.* 1984; Nespolo 1999]: 1) *subfamily-A polytypes:* successive layers are rotated by $2n \times 60°$ only [1*M*, $2M_1$, and 3*T*]; 2) *subfamily-B polytypes:* successive layers are rotated by $(2n+1) \times 60°$ only [$2M_2$, 2*O*, and 6*H*]; 3) *mixed-rotation polytypes:* successive layers are rotated by both $2n \times 60°$ and $(2n+1) \times 60°$ (in all cases $0 \leq n \leq 5$) [...]."

The ideal space-group types of the six homogeneous polytypes are: *C*2/*m* (1*M*), *C*2/*c* ($2M_1$ and $2M_2$), $P3_{1,2}12$ (3*T*), *Ccmm* (2*O*), and $P6_{1,5}22$ (6*H*) [Zvyagin 1962].

4.2 Stacking polytype repartition

As summarized by [Ferraris *et al.* 2001]:

"Subfamily A polytypes are by far more common and among them 1*M* and $2M_1$ are the most abundant in trioctahedral and dioctahedral micas, respectively [Bailey 1984; Abbot &Burnham 1988]. The 3*T* polytype occurs particularly for phengitic compositions, ideally $KAl_{1.5}(Mg,Fe)_{0.5}[Si_{3.5}Al_{0.5}O_{10}](OH)_2$ (see [Ivaldi *et al.* 2001]); its occurrence in trioctahedral micas is also known (e.g. [Ross *et al.* 1966]), but the small number of structural reports might be due to difficulty of distinguishing it from a three-individual twin of 1*M* [... or to ambiguity in indexing the 3*T* polytype (Nespolo & Kogure 1998)]. Subfamily B polytypes are rarer and 6*H* is so far unknown; $2M_2$ occurs mainly in lepidolites (e.g. see [Guggenheim 1981]). A 'non-orthodox' 2*O* polytype has been reported in anandite, $BaFe^{2+}{}_3(Mg,Fe)_{0.5}[Si_3Fe^{3+}O_{10}]OHS$, from Sri Lanka and structurally refined [Giuseppetti & Tadini 1972; Filut *et al.* 1985] in the space-group type *Pnmn*. Because of ordering between S and OH, neither the structure nor its building layers can be described on the basis of *C*-centred cell common to all mica polytypes: this anandite does not represent a true mica polytype. The presence of S seems essential to stabilise the structure, which shows coordination 13 for Ba in the interlayer (12 O plus S). A 2*O* polytype has been reported in a synthetic fluor-phlogopite [Sunagawa *et al.* 1968], on the basis of surface observation only (the space-group type was not investigated), and a short 2*O* sequence has been observed by High Resolution Transmission Electron Microscopy (HRTEM) in a matrix of a [Ti-containing] magnesian annite [Kogure & Nespolo 1999].

[Lazarenko *et al.* 1978] observed by electron diffraction associated $2O$ and $1M$ polytypes of lepidolite, $(K_{1.03}Na_{0.01}Rb_{0.02}Ca_{0.02})$ $(Li_{1.49}Al_{0.89}Fe^{3+}_{0.05}Fe^{2+}_{0.39}Mg_{0.03}Ti_{0.02})$ $(Si_{3.58}Al_{0.42}O_{10})F_{1.59}(OH)_{0.41}$, within fine-lamellar aggregates; no crystal data were reported".

In the above quoted reference [Ferraris *et al.* 2001], the first structure determination of a $2O$ polytype in space-group type *Ccmm* is reported to occur in association with a $1M$ polytype.

Figure 4.1 shows a histogram representing the repartition of the different stacking polytypes amongst the selection of published crystal structures considered in this thesis. In total, two hundred thirty-five (235) mica structures were retrieved from the literature; these are compiled in separate databases for each of the $1M$, $2M_1$, $2M_2$, $2O$ and $3T$ polytypes in Appendices P to T, respectively.

In the case of the $1M$ database, a complete set of crystal structure data (including octahedral, tetrahedral, and interlayer bond lengths and angles, etc.) was extracted from each crystal structure refinement for the purpose of comparisons with simple geometrical models (see Chapter 6).

All crystal structures belonging to the $1M$, $2M_1$, $2M_2$, and $2O$ stacking polytypes are built from the M1 layer type, whereas the $3T$ polytype comprises structures that are built from M1 or M2 layer types (recalling Section 1.1, an M1 layer has the origin of the octahedral sheet in the $M1$site whereas an M2 layer has the origin of the octahedral sheet in either the $M2$ or the $M3$ site). It is important to point out that the selection of structural refinements considered in this thesis amounts to approximately 90 % of all published crystal structure refinements of micas. The remaining 10 % of structural refinements which were not included correspond to homogeneous stacking polytypes refined in subgroup symmetries: $1M$ polytype, space group $C2$ (which comprises structures built by M1 or M2 layer type), $2M_1$ polytype, space groups Cc and $C1$; and $3T$ polytype, space group $C12(1)$ (which also comprises structures built by M1 or M2 layer type) (for examples, see [Brigatti & Guggenheim 2002; Nespolo & Ďurovič 2002]).

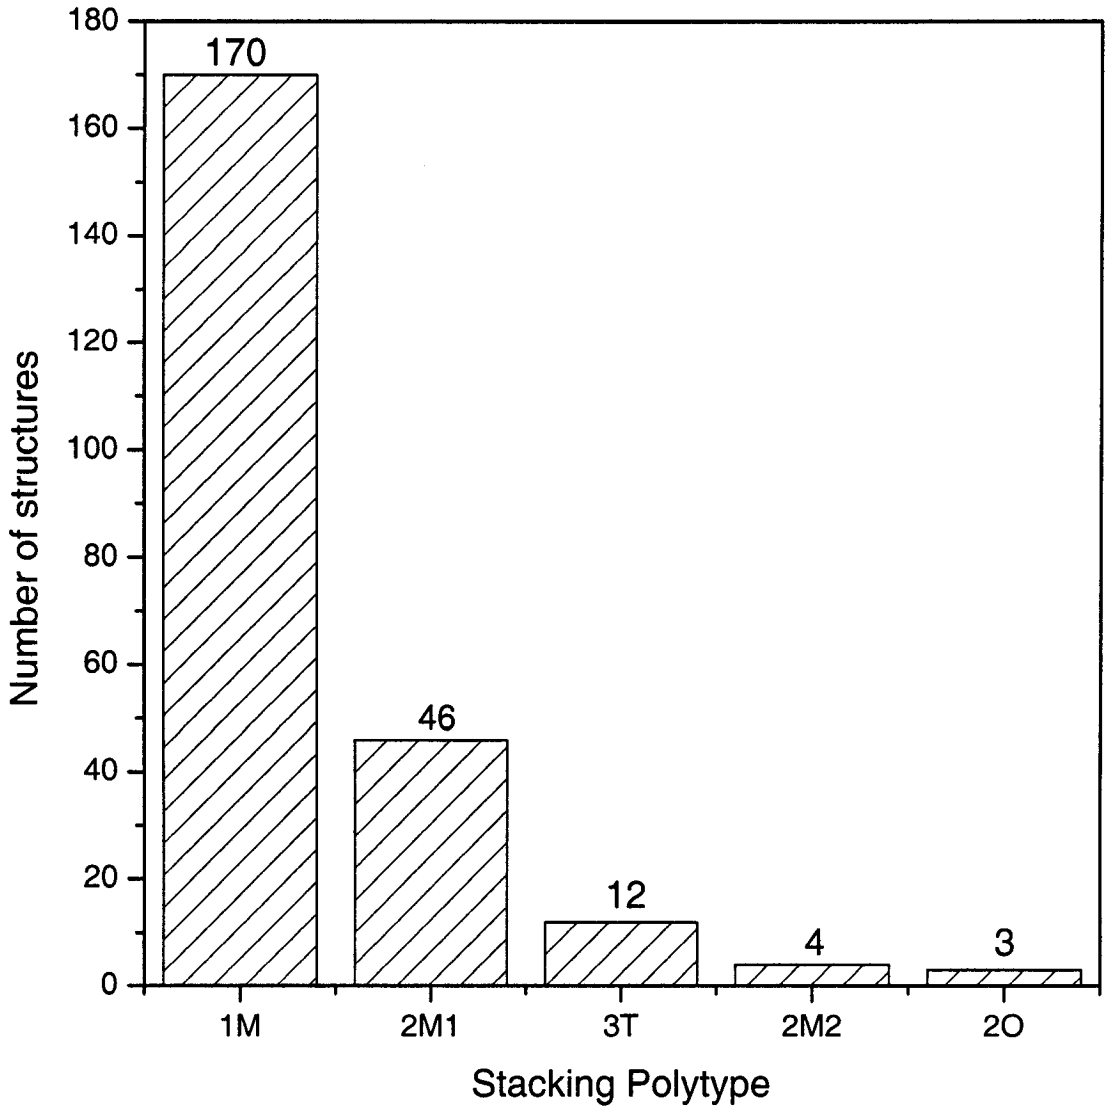

Figure 4.1. Histogram showing the repartition of mica polytypes amongst the selection of published crystal structure refinements (235 samples) considered in this thesis.

4.3 Crystal-structure models for selected stacking polytypes

For each selected stacking polytype (Table 4.1), fractional atomic coordinates were derived in terms of atomic positions in the unit cell of a conventional M layer (standard 1*M* layer). Tables 4.2 to 4.5 give fractional atomic coordinates for the $2M_1$, $2M_2$, $2O$, and $3T$ polytypes, respectively. Since the $6H$ polytype has never been observed in nature and that there exist only one crystal structure refinement of questionable quality for an inhomogeneous mica polytype [Rule *et al.* 1987], fractional atomic coordinates were not worked out for those polytypes.

Following the treatment of [Zvyagin 1962], one can show (see Maple worksheets contained in Appendix U) that these sets of fractional atomic coordinates (Tables 4.2 to 4.5) are exact and self-consistent provided that a few assumptions are made and a few appropriate steps are taken, which can be outlined as follows:

1. Transform fractional atomic coordinates from those of the 1*M* structure to orthogonal trimetric atomic coordinates $x'/a, y/b, z'/c'$, which, according to [Donnay *et al.* 1964]: "can be calculated in a rectangular system of axes Ox, Oy, Oz', in which Ox and Oy are the usual monoclinic axes], Oz' is normal to the cleavage plane (001), and $c' = c \sin\beta^*$ [$= c^*$; $\beta^* = 180° - \beta_{1M}$] is the interplanar distance d(001) [$= d_{001}$]. As consequences we have:

$$z/c = z'/c' ,$$

$$x = x' + z' \cot\beta^* = x' + z \cos\beta^* ,$$

$$x/a = x'/a + (z/c)(c/a)\cos\beta^* \quad " .$$

This coordinate transformation can be done using the transformation matrix 1*M*_to_*abc** listed in Table 4.1. The rectangular system of axes Ox, Oy, Oz' is hereafter referred to as *abc**, whereas the systems of axes of the different stacking polytypes are referred to as abc_{2M_1}, etc.

2. Apply an origin displacement that brings an *M*1 cation at $(0,0,0)_{abc^*}$ by adding translation vector $[1/2 \cdot c_{1M}/a_{1M} \cdot \cos\beta^* , 0 , -1/2]$ to atomic positions obtained from Step 1 above.

3. Build atomic coordinates of each individual n-th layer of the N-layer polytype ($N = 2$ for $2M_1$, $2O$, and $2M_2$; $N = 3$ for $3T$) by carrying out the following procedure:

   i) rotate all atoms of a standard cell about an axis parallel to c^* which goes through $M1$ located at $(0,0,0)_{abc^*}$, so that the orientation of the n-th layer (see Figure 1 of [Zvyagin 1962]) corresponds to its symbol and its respective position in the stacking sequence (Table 4.1) — for example, with polytype $2M_1$, the stacking sequence is $\overline{BA}$, hence $\overline{B}$ and $\overline{A}$ coincide with the first ($n = 1$) and second ($n = 2$) layer, respectively;

   ii) adjust z/c coordinates for all atoms of each n-th layer;

   iii) add an appropriate stacking vector to the rotated atomic coordinates of individual layers having $n \geq 2$;

   iv) add a centring vector that takes $M1$ cations of each n-th layer to their proper symmetry positions with respect to the centre of symmetry of the relevant space group specific for the given polytype — in the case of polytype $3T$, steps iii) and iv) were combined into individual vectors to be added to each n-th layer; and

   v) transform atomic coordinates expressed in the abc^* system to fractional atomic coordinates specific to each stacking polytype — this was accomplished using the appropriate coordinate transformation matrices given in Table 4.1 (see also Appendix U).

In the case of the 3T polytype, once the above procedure was applied, another centring vector needed to be added in order to obtain a set of fractional atomic coordinates consistent with that of [Guven & Burnham 1967 (M1 layer type); Brown 1978 (M2 layer type)].

Rotation matrices given in Table 4.1 are exact if $b_{1M} = \sqrt{3} \cdot a_{1M}$ (or $b = \sqrt{3} \cdot a$; if there are no subscripts in the label of the lattice parameters, this refers to a standard $1M$ cell). This assumption follows from the in-plane pseudo-hexagonal symmetry of mica layers (Section 6.1).

In the treatment presented above and in Table 4.1 below, please note that the Zvyagin's stacking symbols used here [Zvyagin 1962] are the oldest and have since been abandoned by the

author [Zvyagin *et al.* 1979; Zvyagin 1985]. The modern symbols are numerical, the correspondences being 3 – 2 – 1 – 6 – 5 – 4 for $C - \overline{A} - B - \overline{C} - A - \overline{B}$, respectively. Notice also that the complete stacking symbol of a given polytype actually includes three symbols for each TOT layer used in building the stacking sequence: two for each half-layer, one for the interlayer region (which is always 0 in the case of micas). Shortened symbols giving only one digit for each TOT layer within the stacking sequence of a given polytype are also used, but only in cases of polytypes entirely built by M1 layers. For a review of the state-of-the-art in the field of mica polytypes, see [Nespolo & Ďurovič 2002].

Chapter 5. Lattice Parameters and Stacking Polytype Contents

5.1 Lattice parameters: reproducibility, precision, and accuracy

The precision and accuracy of the lattice parameters ultimately depend on the degree of precision and accuracy of the line positions. In this section, I answer the following questions: What method should we use to evaluate the peak positions? What is the error associated to the reproducibility of the position of the diffraction lines? What is the magnitude of the observational error on the line positions in a given diffractogram? To what degree are the line positions accurate? Do we need to correct the line positions for any systematic errors? What is the precision on each of the refined lattice parameters? What is the accuracy on each of the refined lattice parameters?

Throughout this section, the following terms have the following meanings:

i) *reproducibility* refers to a set of diffractograms of a *given smear* collected under an identical experimental configuration, one after the other, and without removing the sample from the holder and replacing it on the diffractometer;

ii) *precision* refers to diffractograms of a *given sample* collected using different smears or different experimental conditions (e.g., different sizes of scatter slit, etc.); and

iii) *accuracy* refers to the uncertainty of a line position or of a lattice parameter when compared to a *certified* value.

5.1.1 Evaluation of the peak positions

In this subsection, I compare the results of two methods that were considered for the evaluation of the Cu $K\alpha_1$ peak positions: i) visual estimation, and ii) line-profile fitting of the diffraction lines using the FP approach implemented in XFIT (Subsection 2.1.4).

With the first method, I carefully examine each diffraction line of a pXRD pattern on an expanded angular scale and visually estimate the angle where the intensity profile of a given diffraction line has a maximum. The software program CELREF Beta Version by Laugier (www.inpg.fr/LMPG/) provides a user-friendly interface to perform this task. This method is simple and is equivalent to other common methods that rely on peak-finding routines based on second-derivative algorithms.

The separation of the $K\alpha_1$ and $K\alpha_2$ line, $\Delta\theta_{\alpha_1-\alpha_2}$, increases with the diffraction angle as

$$\Delta\theta_{\alpha_1-\alpha_2} = 2\left(\frac{\Delta\lambda}{\lambda}\right)\tan\theta \quad \text{(in radians)}, \tag{5. 1}$$

where $\Delta\lambda = \lambda_{\alpha_2} - \lambda_{\alpha_1}$ and $\lambda = \left(\lambda_{\alpha_2} + \lambda_{\alpha_1}\right)/2$. The $K\alpha$ doublet thus contributes a certain amount of broadening to a diffraction line. However, the intensity of the $K\alpha_1$ line is approximately twice as that of the $K\alpha_2$ line. So the broadening induced is asymmetric in nature. In the cases where the $K\alpha$ doublet is well resolved, we unambiguously assign $K\alpha_1$ line positions to the peaks with the lower 2θ values. In other cases where the $K\alpha$ doublet is not resolved, the $K\alpha_2$ contribution always appears as a shoulder on the high-angle side of the diffraction line and is progressively less apparent as 2θ decreases. In light of the above considerations, it is therefore correct (as a first-approximation) to attribute the Cu $K\alpha_1$ position to the angle corresponding to the maximum intensity of a diffraction line.

With the second method, I carry out a line-profile fitting for each diffraction line observed in a diffractogram using the FP approach implemented in XFIT (Subsection 2.1.4). I utilized a LAM file containing the data of Table 2.1 to generate the emission profile of a peak. The background was modelled as up to a 9th order orthonormalized Chebyshev polynomial. For each peak, a unique CS parameter was found sufficient to adequately model each line-profile, so that no other specimen-dependent parameters were adjusted. All diffractometer-dependent parameters were fixed at the actual values of the experimental configuration; namely, TA = 0.04 mm, ST = 0 mm, SW = 0.1 mm, SL = 18 mm, SAML = 10 mm (the size of the beam mask used),

SOUL = 12 mm, PS = 2.3°, and SS = 2.3°. In addition, I imposed a FSFL = 12 mm or a FSFA = 1° or 2°, which ever was appropriate, in order to properly account for the combination of divergent and scatter slits used in recording the diffractograms (as explained in Chapter 2, see explanations leading to Eqns. 2.1 to 2.4).

I have determined the $K\alpha_1$ line positions by these two methods for several diffractograms from samples IKO-Ann and $Ni_{3.0}$JLR, and from various standard reference materials (SRMs): SRM640b, silicon powder [Raspberry, 1987]; SRM640c, silicon powder [Freiman & Trahey 2000a]; and SRM660a, lanthanum hexaboride powder [Freiman & Trahey 2000b] (see Appendix V for details).

Table V.1 (Appendix V) compares the results yielded by each method. The $K\alpha_1$ line positions determined by the visual estimation method, $2\theta_{vis}$, the $K\alpha_1$ line positions obtained by the FP line-profile fitting method, $2\theta_{prf}$, and the differences between $K\alpha_1$ line positions extracted by each method, $\text{Diff.} = 2\theta_{vis} - 2\theta_{prf}$, are tabulated in separate columns. The average value of the differences $2\theta_{vis} - 2\theta_{prf}$ corresponding to a single diffractogram, <Diff.>, and the standard deviation of these differences, $\sigma_{Diff.}$, excluding outliers, are indicated at the bottom of the column corresponding to each diffractogram. Outliers always coincide with diffraction lines having weak intensities.

Additionally, Figures 5.1 and 5.2 illustrate the results of Table V.1 for various diffractograms measured on the left and right goniometers, respectively. On both Figures 5.1 and 5.2, each graph shows the differences, $\text{Diff.} = 2\theta_{vis} - 2\theta_{prf}$, for the various peaks observed in a single diffractogram. For each diffractogram, the values of <Diff.> and $\sigma_{Diff.}$ are also indicated.

For the diffractograms collected from acetone smears of sample IKO-Ann on either the left or right goniometer, the behaviours of the differences displayed are the same for all diffractograms. The values of <Diff.> and $\sigma_{Diff.}$ range from -0.0012 to 0.0213 °2θ and from 0.0140 to 0.0277 °2θ, respectively (Table V.1, Appendix V). The values of <Diff.> are mostly positive, indicating that the visual estimation method usually gives 2θ values that are slightly greater than the FP line-profile fitting method. However, the <Diff.> values are of the same order or less than the $\sigma_{Diff.}$ values, thereby revealing that these systematic differences are relatively

small compared to the width of the distribution of the differences $\text{Diff.} = 2\theta_{vis} - 2\theta_{prf}$ for a given diffractogram.

In the case of diffractograms measured on the left goniometer from SRMs, the values of Av. Diff. and $\sigma_{Diff.}$ range from -0.0054 to 0.0014 °2θ and from 0.0009 to 0.0068 °2θ, respectively; on the right goniometer, Av. Diff. and $\sigma_{Diff.}$ take on values of 0.0043 and 0.0088 °2θ and of 0.0064 and 0.0092 °2θ, respectively.

On the left goniometer, differences demonstrated by SRMs have <Diff.> and $\sigma_{Diff.}$ values which are approximately one order of magnitude smaller. It can also be noted that four <Diff.> values are positive and two others are negative. The reflections of the SRMs are much thinner than diffraction lines observed from acetone smears of sample IKO-Ann, because SRMs introduce a minimal amount of sample-induced line broadening. As a result, the peak positions are much more constrained and the resolution of the diffraction lines is better.

The distinctions between differences in line positions from acetone smears of sample IKO-Ann and those of SRMs are clearly exhibited in Figures 5.1 and 5.2. We can observe that the scatter is much larger for the IKO-Ann graphs than in the graphs corresponding to mixtures of SRMs. Further, the scatter of IKO-Ann graph does not seem to vary with the evolution of the 2θ angle for both goniometers (Figures 5.1 and 5.2).

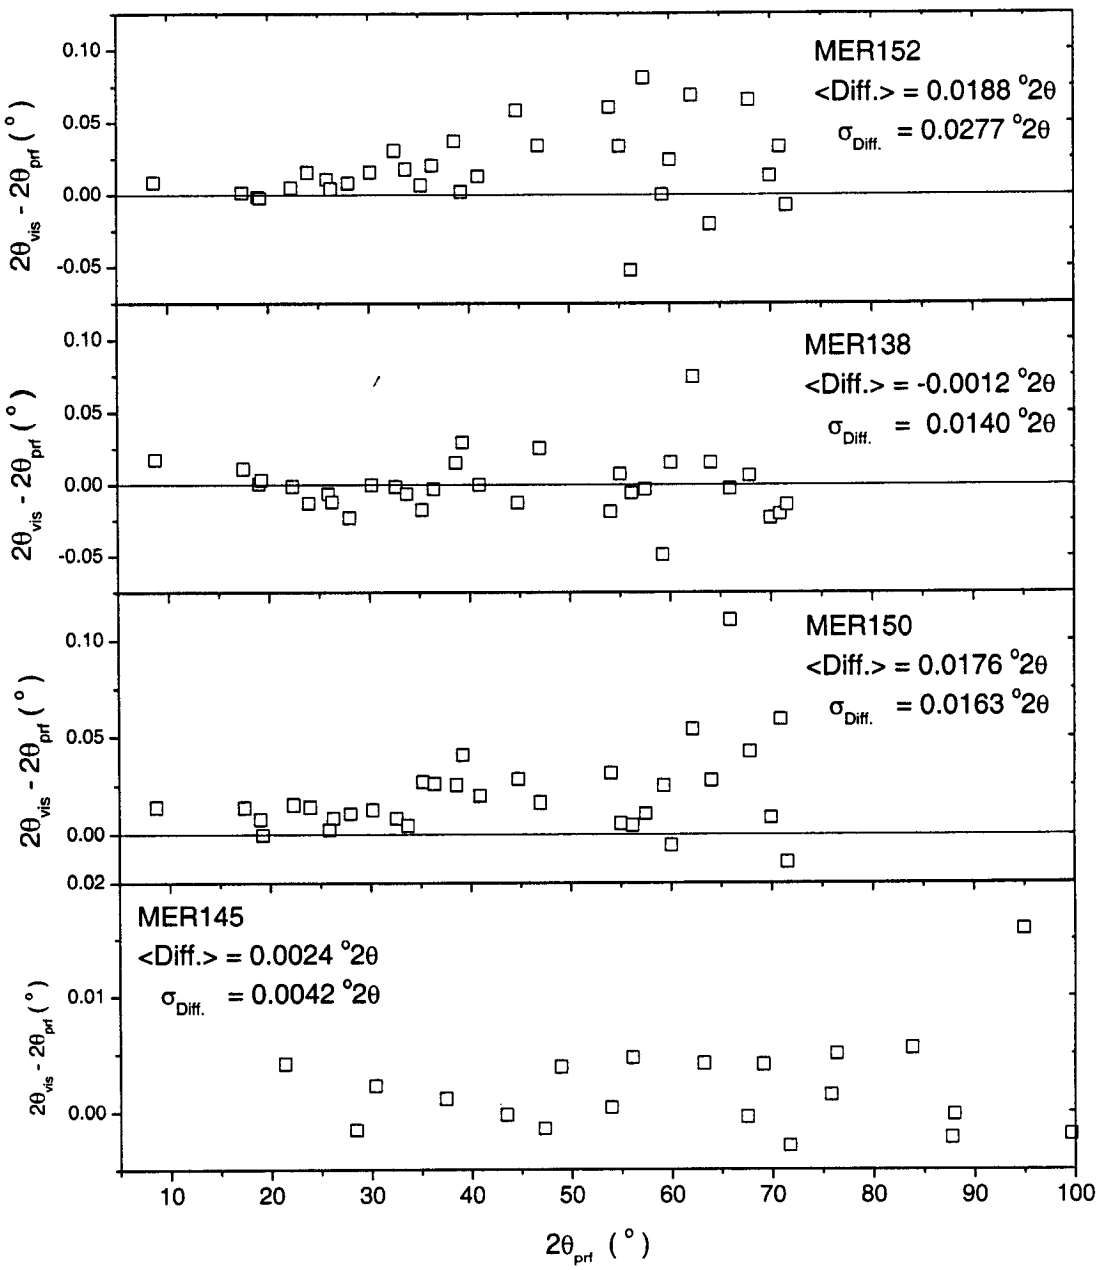

Figure 5.1. Comparison of $K\alpha_1$ line positions obtained by the visual estimation and FP line-profile fitting methods for selected diffractograms measured on the left goniometer (see text for a description of the content of the figure).

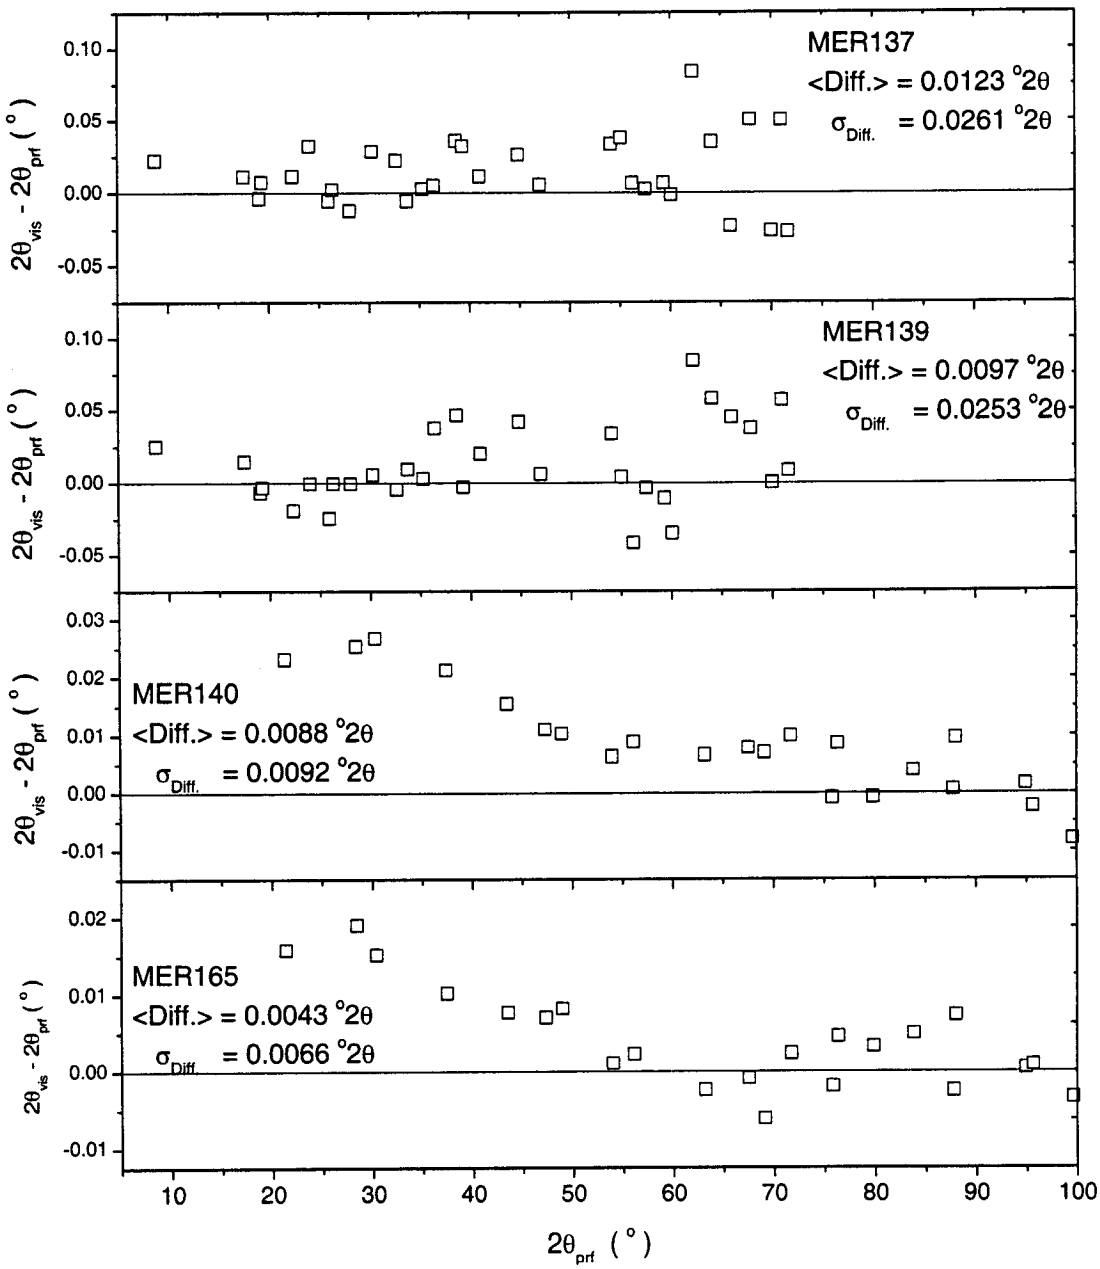

Figure 5.2. Comparison of $K\alpha_1$ line positions obtained by the visual estimation and FP line-profile fitting methods for selected diffractograms measured on the right goniometer (see text for a description of the content of the figure).

Assuming that the measurement errors of line positions in a given diffractogram can be determined for each method, and since $\sigma_{Diff.}$ is proportional to $\sqrt{\sigma_{vis}^2 + \sigma_{prf}^2}$ (assuming uncorrelated errors into error propagation), where σ_{vis} and σ_{prf} are the measurement errors of line positions in a given diffractogram evaluated by visual estimation and FP fitting, respectively, then the fact that $\sigma_{Diff.}$ values are approximately one order of magnitude larger for IKO-Ann than for SRMs means that line positions are established more precisely in the case of SRMs. I will estimate the measurement errors of each method in the next two subsections.

In the case of the right goniometer, Figure 5.2 also shows that the scatter in the IKO-Ann graphs is much larger than in those of SRMs. On the other hand, we notice a systematic increase in the differences below $2\theta \approx 50^0$ as the diffractometer angle decreases in the case of SRMs (Figure 5.2).

I impute this artifact to the following factors: i) the Kevex detector of the right goniometer yields more counts for the same sample than the gas-filled proportional counter of the left goniometer, thereby causing the resolution of the reflections and the signal-to-noise to be augmented on the right goniometer; ii) the asymmetry of the peak is larger on the right than on the left goniometer because axial divergence is enhanced due to the smaller radius of the right goniometer; iii) as a result of i) and ii), the peaks on the right goniometer can be observed with high enough resolution and asymmetry to give rise to the systematics described above.

In summary, I conclude that: i) for diffractograms measured on the left goniometer from both IKO-Ann and SRMs, as well as for diffractograms recorded on the right goniometer from IKO-Ann, the visual estimation method gives $K\alpha_1$ line positions that are slightly greater than those obtained by the FP line-profile fitting method; and ii) in the case of diffractograms from SRMs recorded on the right goniometer, the differences between the $K\alpha_1$ line positions obtained by the two methods significantly augment as 2θ decreases when the diffractometer angle is below $2\theta \approx 50^0$. In the next three subsections, I will determine the precision and accuracy associated to each method and establish the extent to which these relatively small peak position differences play an important role.

5.1.2 Reproducibility of the peak positions

In order to find out the reproducibility of the peak positions, three diffractograms (MER151, MER152, and MER153) of a single smear of sample IKO-Ann were collected on the left goniometer under an identical experimental configuration, one after the other, and without removing the silicon wafer from the sample holder and putting it back in between each measurement. This sequence of measurements allows one to single out the following factors of the many sources of error: i) peculiarities of the diffraction patterns of the samples (i.e., degree of overlap of reflections, line broadening due to microstructural properties, etc.); ii) the quality of the experimental data (i.e., signal-to-noise, degree of resolution of the reflections, etc.); and iii) instrumental contributions related to the control of the goniometer's 2θ positions, the variable divergence slit, and the receiving slit.

Having evaluated the $K\alpha_1$ line positions of each peak j observed in the diffraction pattern of sample IKO-Ann for each of the diffractograms MER151-152-153 separately (Table V.1), by both the visual estimation and the FP line-profile methods, I have computed the average position of each reflection j as:

$$2\theta_j^{mean} = \frac{1}{K}\sum_{k=1}^{K} 2\theta_{j,k} \quad , \tag{5.2}$$

where k designates a particular diffractogram in the set of K diffractograms. Then, the standard deviation of the position of the j-th reflection is given by:

$$\sigma_j = \sqrt{\frac{1}{K-1}\sum_{k=1}^{K}\left(2\theta_{j,k} - 2\theta_j^{mean}\right)^2} \quad . \tag{5.3}$$

With $K = 3$, however, it must be realized that the σ_j values overestimate the measurement error of the position of a given reflection in most cases.

I have also computed the average value, $\left(\sigma_j\right)_{av}$, and standard deviation, $\left(\sigma_j\right)_{sd}$, of the σ_j values. If we assume that the σ_j values are independent measurements of the error in the peak position at various 2θ angles across a diffractogram, and that the nature of the errors is the same for all peaks at all 2θ, then: i) $\left(\sigma_j\right)_{av}$ represents an estimation of the overall magnitude of the observational error on the line positions in a given diffractogram; and ii) $\left(\sigma_j\right)_{sd}$ gives a measure of the uncertainty of $\left(\sigma_j\right)_{av}$.

Figure 5.3 shows the standard deviations, σ_j, versus mean position, $2\theta_j^{mean}$, of each diffraction peak j computed from the measured $K\alpha_1$ line positions on diffractograms MER151-152-153 (Table V.1). The average value, $\left(\sigma_j\right)_{av}$, and standard deviation, $\left(\sigma_j\right)_{sd}$, of the σ_j values, obtained using relations similar to those of Eqns. 5.2 and 5.3 (excluding the outliers that are circled on each graph), are indicated on the graph corresponding to each method. Since diffractograms MER151-152-153 correspond to repeated measurements under an identical experimental configuration, the $\left(\sigma_j\right)_{av}$ and $\left(\sigma_j\right)_{sd}$ values reported in Figure 5.3 provide an estimate of the reproducibility error on the peak positions from our samples for each method.

The visual estimation method gives $\left(\sigma_j\right)_{av}$ and $\left(\sigma_j\right)_{sd}$ values of 0.016 and 0.013 °2θ, respectively, whereas those obtained by FP line-profile fitting are approximately three times smaller, yielding $\left(\sigma_j\right)_{av}$ and $\left(\sigma_j\right)_{sd}$ values equal to 0.0054 and 0.0042 °2θ, respectively. Thus, the FP line-profile fitting method is more precise than that of visual estimation in terms of determining the peak positions for our samples.

In conclusion, because of the reproducibility error, the ultimate precision of the $K\alpha_1$ line positions which can be achieved is of 0.005 to 0.01 °2θ with the FP line-profile fitting method and of 0.01 to 0.02 °2θ with the visual estimation method.

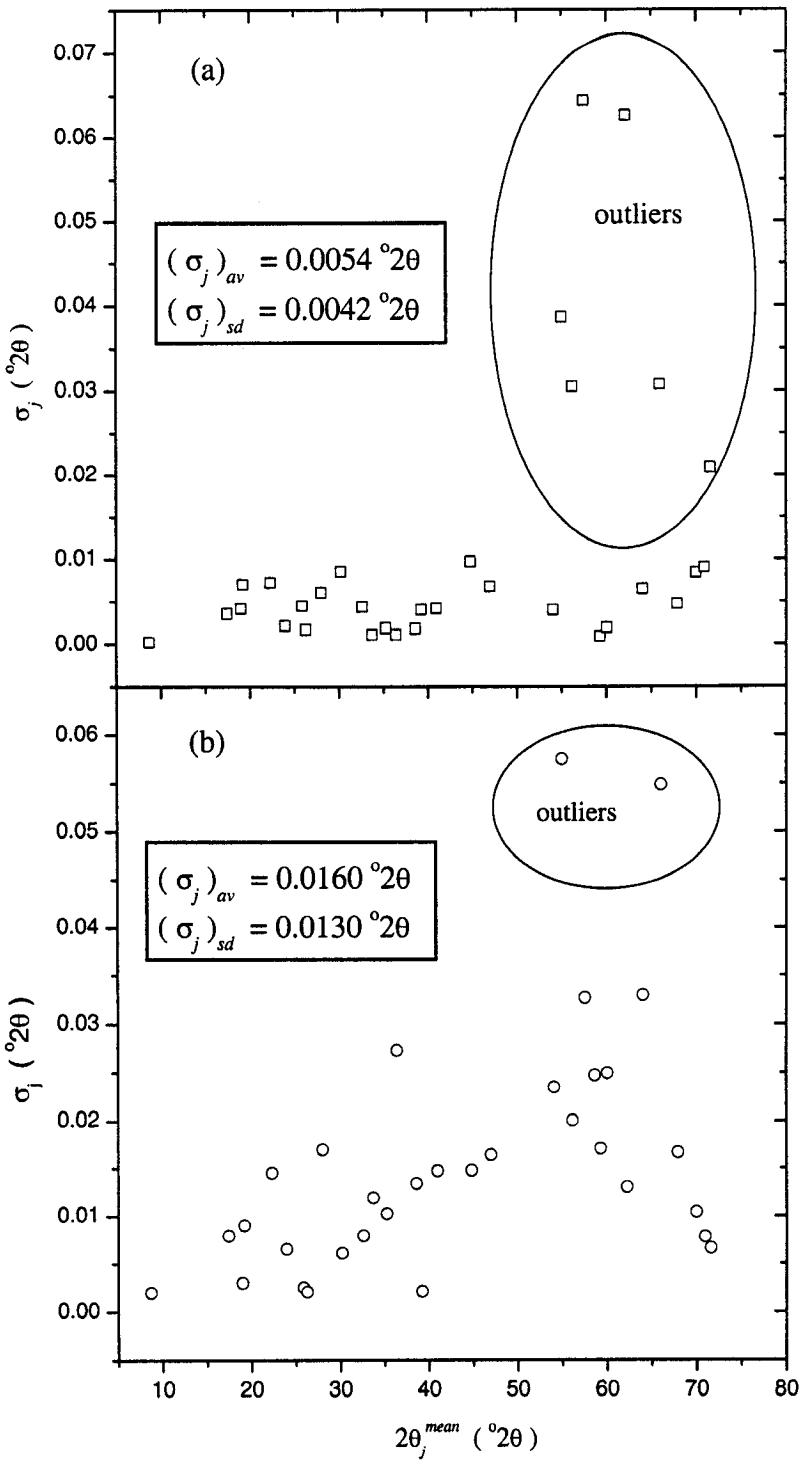

Figure 5.3. Reproducibility error evaluated by: (a) the FP line-profile fitting method, and (b) the visual estimation method. Symbols are explained in the text, along with a description of the content of the figure.

5.1.3 Precision and accuracy of the peak positions

Besides the random reproducibility error, that is mainly determined by the noise level in the data, systematic and non-statistical random errors are attributable to a combination of the following factors: uniformness of smears (thickness, distribution of material over the diffracting sample area, etc.), exact position of goniometer's reference surface from one measurement to another (i.e., the effect of putting the sample in and out), amount of noise present (tolerated) in the data, differences in experimental configurations (e.g., different sizes of scatter slit, etc.), and sample-dependent properties (e.g., degree of overlap between reflections, particle-size broadening, etc.).

Table V.2 (Appendix V) compares values of $\left(\sigma_j\right)_{av}$ and $\left(\sigma_j\right)_{sd}$ computed from $K\alpha_1$ line positions reported in Table V.1 for various sets of diffractograms. For sets of diffractograms from IKO-Ann and for both the visual estimation and the FP line-profile fitting methods, one sees that $\left(\sigma_j\right)_{av}$ and $\left(\sigma_j\right)_{sd}$ values are of the same order as those established in the preceding subsection for the reproducibility error. Thus, it seems that factors external to those associated to the reproducibility error do not significantly augment the magnitude of the observational error on the peak positions for diffractograms from sample IKO-Ann. Since the diffractograms of all the samples are similar to those of IKO-Ann, I therefore conclude that the peak positions in a given diffractogram can be measured within a precision of ~0.0075 °2θ with FP line-profile fitting and of ~0.015 °2θ with visual estimation.

Note also that $\left(\sigma_j\right)_{av}$ and $\left(\sigma_j\right)_{sd}$ values obtained from considering diffractograms of SRMs are approximately the same for both the visual estimation and the FP line-profile fitting methods, ranging from 0.0010 to 0.0050 °2θ for both $\left(\sigma_j\right)_{av}$ and $\left(\sigma_j\right)_{sd}$. As explained earlier, because SRMs introduce a minimal amount of sample-induced line broadening, the resolution of the diffraction lines is better and the peak positions are more constrained. So in the case of SRMs, the peak positions can be measured with a precision error smaller than 0.005 °2θ with either visual estimation or FP line-profile fitting.

Let us turn to the accuracy of the line positions. Figures 5.4 (left goniometer) and 5.5 (right goniometer) compare 2θ values determined from certified SRMs's lattice parameters [Freiman & Trahey 2000a, 2000b; Raspberry 1987], $2\theta_{cert.}$, to $K\alpha_1$ line positions evaluated by

visual estimation and FP fitting, assuming $\lambda_{\alpha_1} = 1.5406$ Å.

The diffractograms referred to in Figures 5.4 and 5.5 were ran at various points in time. For the sets of measurements ran in November 2001 (MER140-145-148 and SRM640c_6NOV2001) and March 2002 (MER154-165), on both the left and right goniometers, one sees that the scatter on the y-axis of all graphs of Figures 5.4 and 5.5 is of the order of the precision error on line positions from SRMs established earlier in the current subsection, such that all points, within an uncertainty of ±0.005 °2θ, usually follow monotonic decreasing trends in going from low to high angles.

On the left goniometer, for measurements ran in November 2001 and March 2002, the points scatter around values of $\left(2\theta_{vis} - 2\theta_{cert.}\right)$ and $\left(2\theta_{prf} - 2\theta_{cert.}\right)$ nearly equal to zero for all $2\theta_{cert.}$ values, except for a slight interval towards lower $2\theta_{cert.}$ values where small positive values of $\left(2\theta_{vis} - 2\theta_{cert.}\right)$ and $\left(2\theta_{prf} - 2\theta_{cert.}\right)$ are observed as the general trend. The latter feature is more pronounced with the visual estimation method. On the other end, MER064 (November 1998) and s002_hkl (March 1999) display net differences $\left(2\theta_{vis} - 2\theta_{cert.}\right)$ and $\left(2\theta_{prf} - 2\theta_{cert.}\right)$ ranging from 0.030 and 0.025 °2θ with visual estimation and FP fitting, respectively, at low $2\theta_{cert.}$ values, down to approximately zero as $2\theta_{cert.}$ increases. The decrease is more regular with FP fitting.

On the right goniometer, values of differences $\left(2\theta_{vis} - 2\theta_{cert.}\right)$ diminish monotonically from 0.010 °2θ at 20° to -0.025 °2θ at 100°. As for the differences $\left(2\theta_{prf} - 2\theta_{cert.}\right)$, they first evolve on a plateau at -0.015 °2θ up to $2\theta \approx 50^0$, and then decrease progressively to -0.025 °2θ at 100°. This difference in behaviour of line positions from visual estimation and FP fitting on the right goniometer has already been explained in the context of Figure 5.2.

In summary, Figures 5.4 and 5.5 provide the state of the goniometers's alignment at the times specified above. Corrections to line positions for any systematic errors would have to come, at least partially, from considerations related to these two figures. However, as will be demonstrated in the next subsection, given the precision error on the refined lattice parameters, no such corrections are necessary.

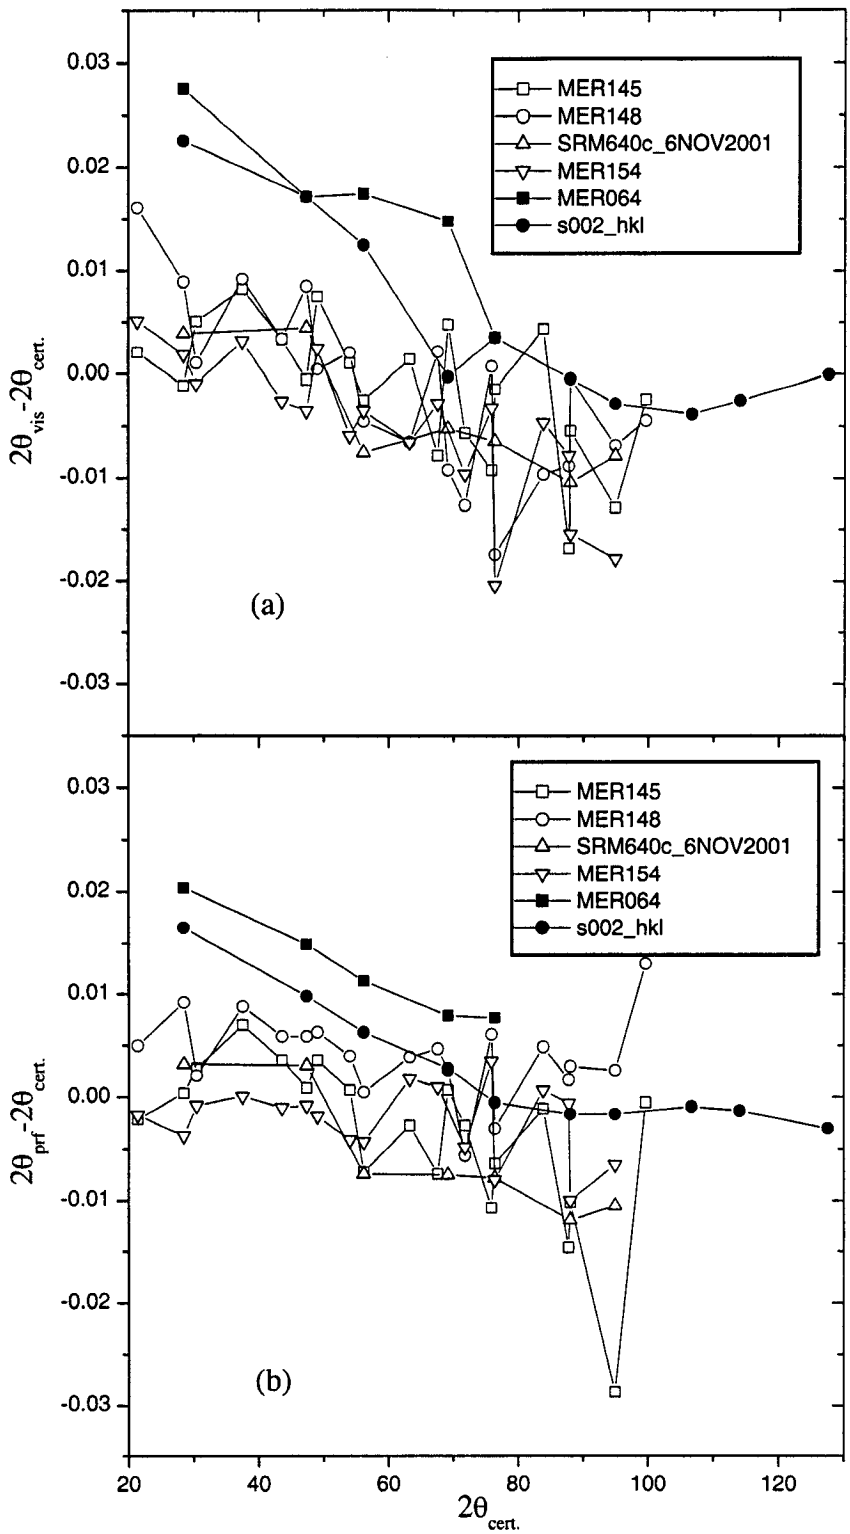

Figure 5.4. Comparison of certified 2θ values of SRMs to $K\alpha_1$ line positions determined on the left goniometer by : (a) visual estimation, and (b) FP line-profile fitting (see text for a description of the content of the figure).

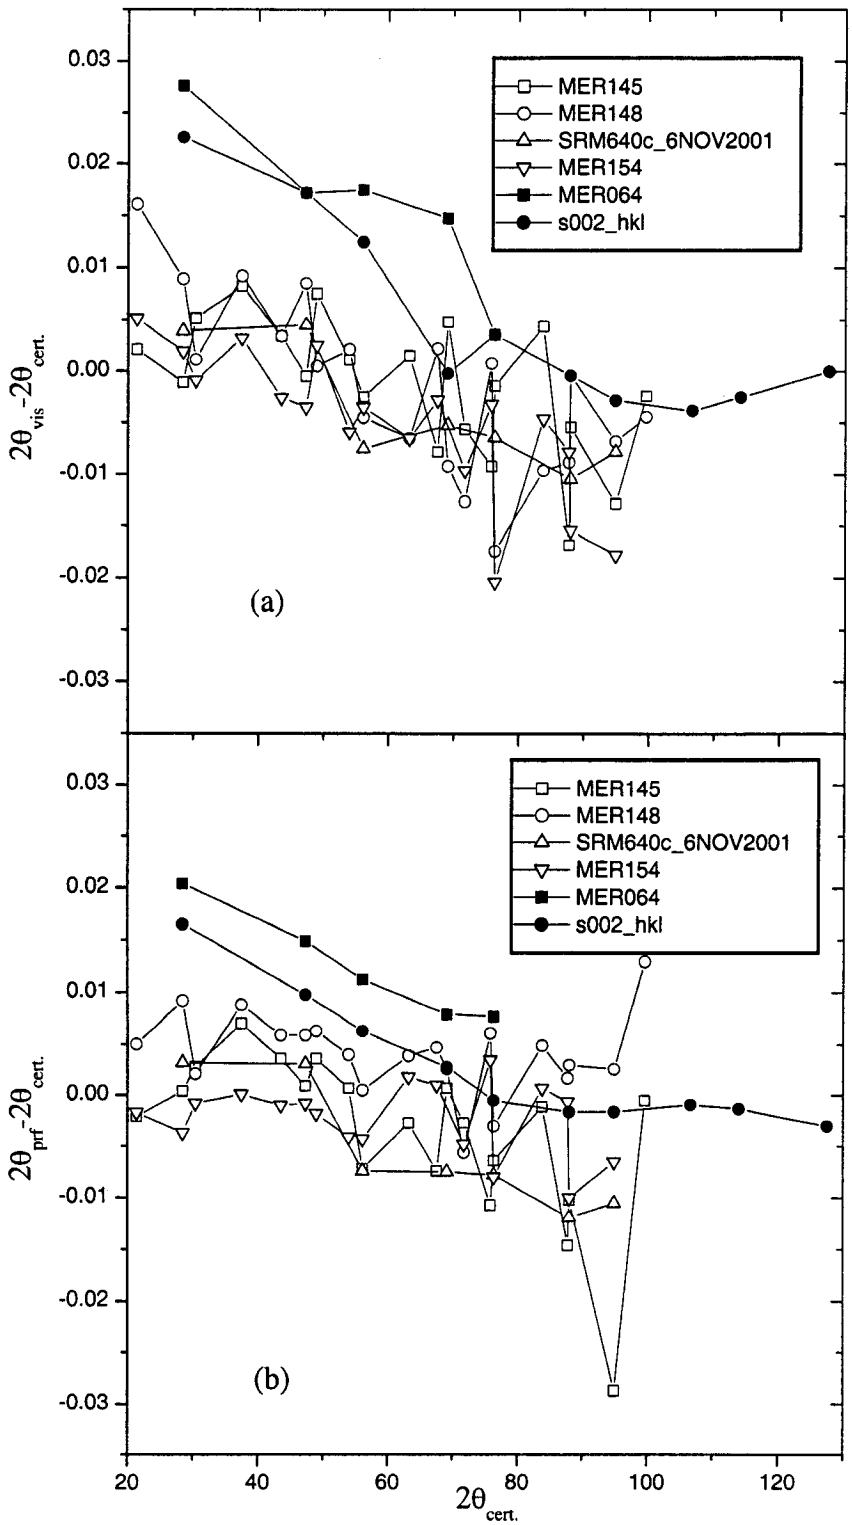

Figure 5.5. Comparison of certified 2θ values of SRMs to $K\alpha_1$ line positions determined on the right goniometer by : (a) visual estimation, and (b) FP line-profile fitting (see text for a description of the content of the figure).

5.1.4 Precision and accuracy of the lattice parameters

Lattice parameters were refined using 23 to 35 reflections for each sample. Indexing was done assuming the 1*M* stacking polytype following Table 5.1, so that 40 to 55 *hkl* values were assigned successfully in each of the diffractograms. Results of all lattice parameter refinements performed for each of the samples (which are obtained from CELREF output files) are tabulated in Appendix W.

Table 5.1 also gives the results of a structure factor calculation performed with the Koalariet program (Section 2.1.4) using the fractional coordinates of [Donnay *et al.*1964] with: a = 5.3948 Å, b = 9.3440 Å, c = 10.3557 Å, $\beta = 100°$, d_o = 2.090 Å, and d_i = 1.680 Å. On the basis of that calculation, all reflections were given equal weight in a given refinement.

Figures 5.6, 5.7, 5.8, and 5.9 compare values of lattice parameters a, b, c, and β, respectively, determined from various diffractograms of samples IKO-Ann and $Ni_{3.0}$JLR with $K\alpha_1$ line positions evaluated by visual estimation and FP fitting. The line positions were not corrected for any systematic errors. The letters A, B, and C refer to groups of diffractograms ran on a given diffractometer at different points in time.

In Figures 5.6-5.10, the solid lines that are shown through the lattice parameters obtained from IKO-Ann diffractograms MER149-153 correspond to a different indexing scheme, where only one *hkl* value was assigned per 2θ reflection. One immediately notes that the scatters of the lattice parameters gets larger as a result of such a procedure. Given what is known about the structure of these materials (Table 5.1), therefore, the latter indexing scheme is wrong, whereas the one of Table 5.1 is more appropriate.

For sample IKO-Ann, values of a (Figure 5.6) cluster around three different values depending on the diffractograms considered: ~5.393 Å for MER135, MER137, and MER139; ~5.394 Å for MER136 and MER138 (left goniometer, Fall 1999; see Table V.2); and ~5.397 Å for MER149 to MER153 (left goniometer, Fall 2000). As for sample $Ni_{3.0}$JLR, values of a determined from line positions evaluated by FP fitting are systematically higher than those refined using line positions visually estimated. Values of a can again be divided into three separate groups for sample $Ni_{3.0}$JLR: ~5.300 Å for MER143; ~5.297 Å for MER131; and ~5.299

Å for MER146 and MER147.

Lattice parameter *b* values (Figure 5.7) closely mirror the behaviours displayed by *a*. Values of *b* for the first, second, and third group of sample IKO-Ann diffractograms are of ~9.342, ~9.343, and ~9.345 Å, respectively. As for sample $Ni_{3.0}$JLR, values of *b* refined are of ~9.180, ~9.175, and ~9.178 Å, for the first, second, and third groups, respectively. More importantly, for almost each case where the value of *b* established by FP fitting is smaller than the one determined from visual estimation, the opposite trend is observed for *a*, and vice-versa. The latter behaviour is true for all $Ni_{3.0}$JLR diffractograms considered and for most of IKO-Ann diffractograms as well.

Lattice parameter *c* values (Figure 5.8) clearly divide themselves into separate groups according to the method that was used to determine the line positions, so that values of *c* obtained from visual estimation are systematically lower than those from FP fitting. With IKO-Ann, FP fitting values level at ~10.324, ~10.328, and ~10.332 Å, for the first, second, and third group, respectively, while those from visual estimation range from ~10.316 to ~10.328 Å and do not clearly distribute themselves into specific groups. In the case of sample $Ni_{3.0}$JLR, values of *c* from visual estimation fall between ~10.276 to ~10.284 Å, whereas those from FP fitting are of ~10.288, ~10.282, and ~10.286 Å for the first, second, and third group, respectively.

Lattice parameter β values (Figure 5.9) show a systematics inverse to that of *c*: in most cases, values of β from visual estimation are higher than those from FP fitting. For sample IKO-Ann, β values from visual estimation range from ~100.04° to ~100.06°, and those from FP fitting are of ~100.04° for the first group, and of ~100.035° for the second and third group. As for sample $Ni_{3.0}$JLR, values of *b* cover an interval between ~99.88° to ~99.90° with both visual estimation and FP fitting.

Let us now establish the precision of the refined lattice parameters. Figure 5.10 compares: i) standard deviations of lattice parameter values evaluated from diffractograms MER149 to MER153 by visual estimation and FP fitting; ii) standard deviations errors calculated by a synthetic method that uses a predefined Gaussian error width to generate 100 different line position data sets for each lattice parameter refinement (the code of the program used for that purpose is given in Appendix X); and iii) estimated standard deviations (ESDs) output by the

CELREF program (which is based on a linear least-squares refinement).

Although the measurement errors of line positions are more precise by FP fitting than by visual estimation (Subsection 5.1.3), it does not seem that the precision of the refined lattice parameters is influenced by the method used to measure the line positions. Indeed, the standard deviations of lattice parameters determined from diffractograms MER149 to MER153 are of the same order of magnitude for both the visual estimation and FP fitting methods. Likewise, the standard deviations calculated by the synthetic method evolve in the same manner for both methods as the assumed Gaussian error width is increased. In the case of ESDs, most of them are slightly larger with visual estimation, but remain of the same order of magnitude as those from FP fitting.

However, lattice parameters extracted from visual estimation and FP fitting differ systematically. The differences exhibited by the refined values of a, b, c, and β for each method are mainly due to the fact the visual estimation method generally gives higher 2θ positions than the FP fitting method (Subsection 5.1.1). Consequently, this causes lattice parameter tradeoffs to occur to accommodate for that effect. Besides that, diffractograms were measured under various state of goniometer's alignment on either side.

In view of all of the above considerations, I conclude that: i) the precision of the lattice parameter measurements is the same with either visual estimation or FP fitting; ii) the one standard deviation (1σ) *precision* errors of lattice parameters are 0.001 Å in a and in b, 0.003 Å in c, and 0.01° in β ; and iii) the 1σ accuracy of the lattice parameters are 0.005 Å for a and b, 0.01 Å for c, and 0.02° for β.

Table 5.1. Indexing scheme followed for the determination of lattice parameters using the CELREF program (Subsection 2.1.3). Also shown are structure factor F^2_{hkl} values that are explained in text. The framed *hkl* values were assigned together to a given 2θ position.

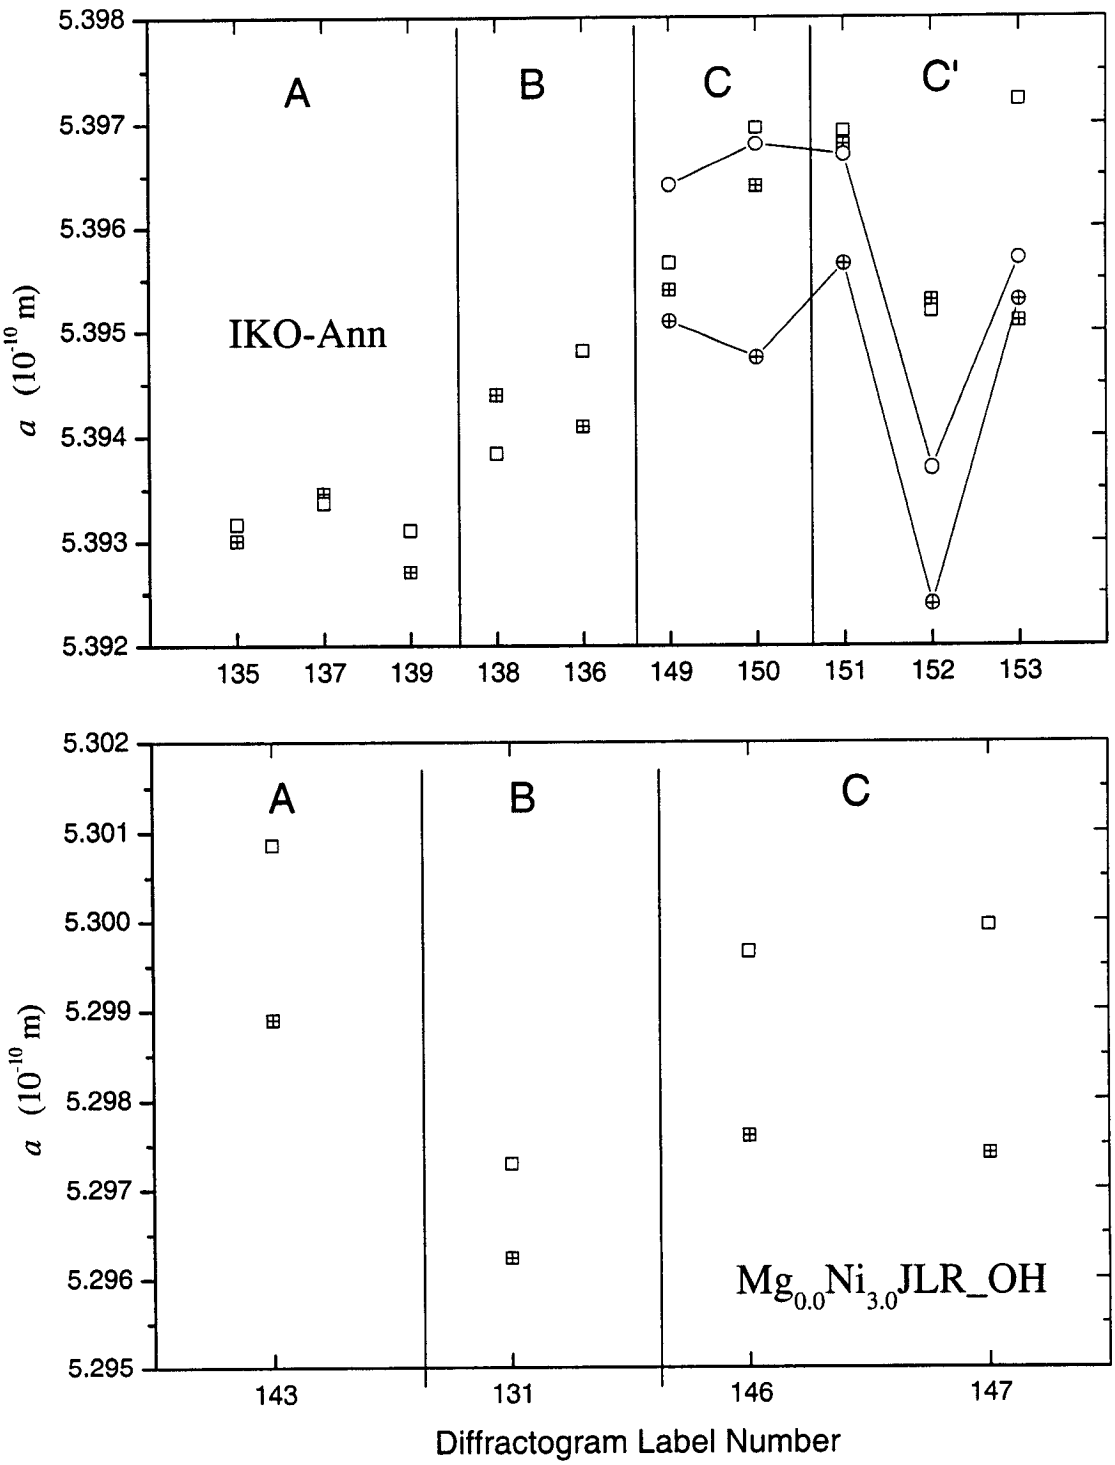

Figure 5.6. Values of lattice parameter a determined from various diffractograms of samples IKO-Ann (top) and $Ni_{3.0}$JLR (bottom) with $K\alpha_1$ positions evaluated by visual estimation (plus-squares) and FP fitting (open-squares).

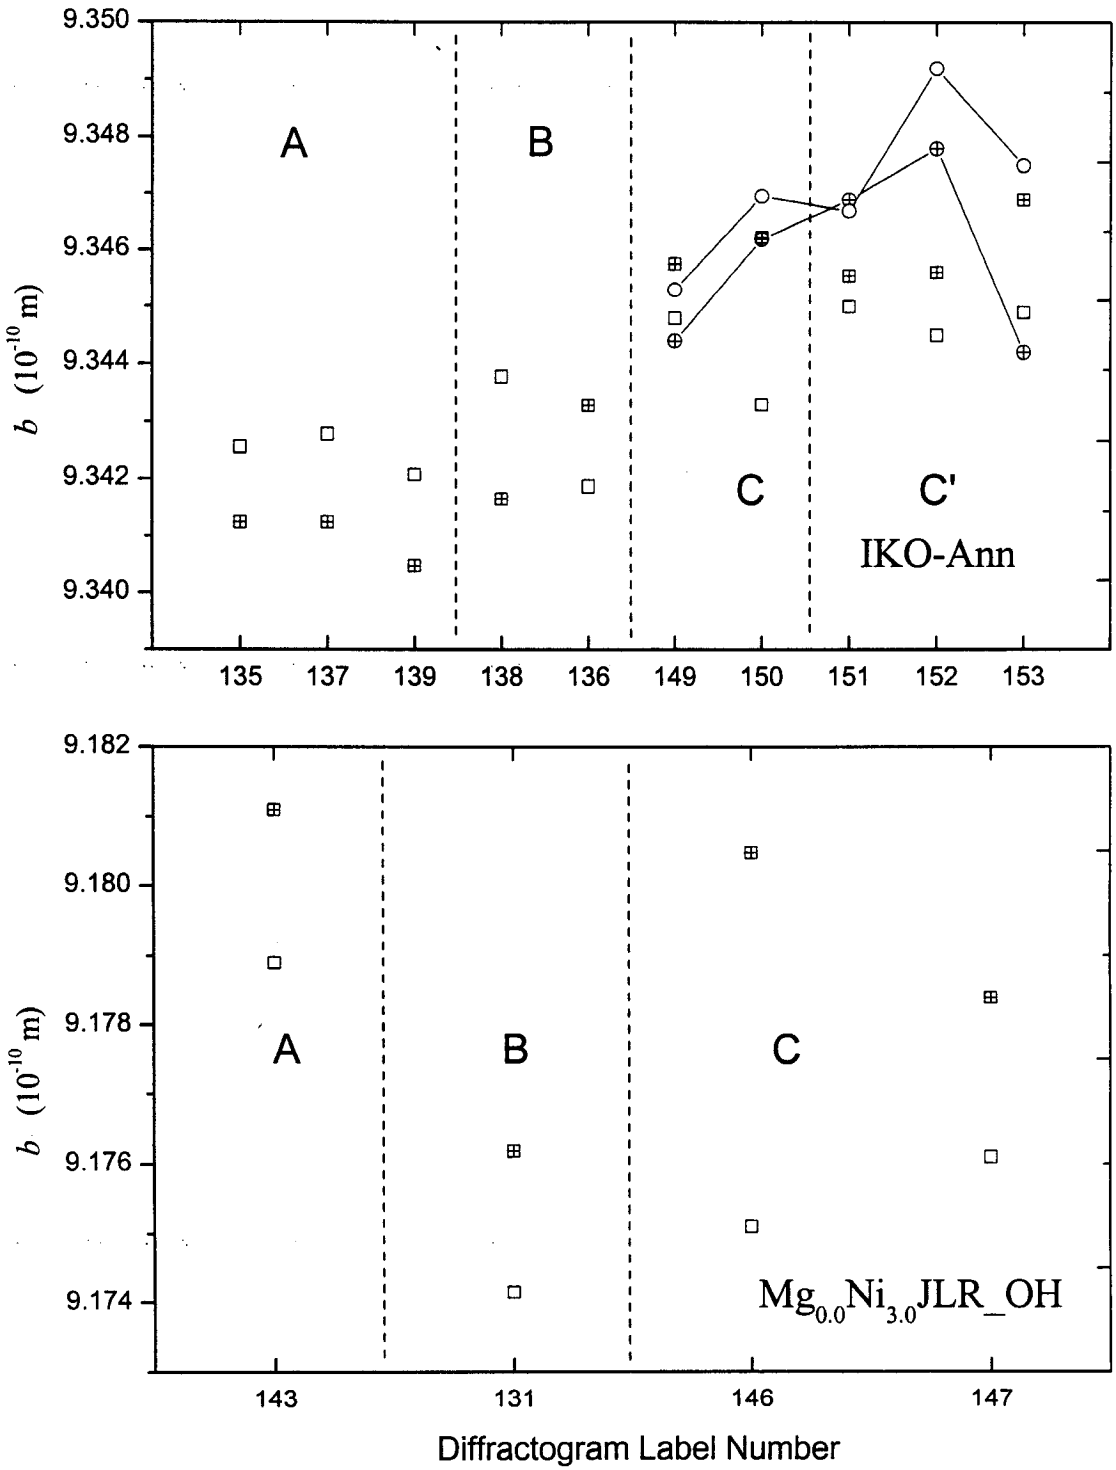

Figure 5.7. Values of lattice parameter b determined from various diffractograms of samples IKO-Ann (top) and $Ni_{3.0}$JLR (bottom) with $K\alpha_1$ positions evaluated by visual estimation (plus-squares) and FP fitting (open-squares).

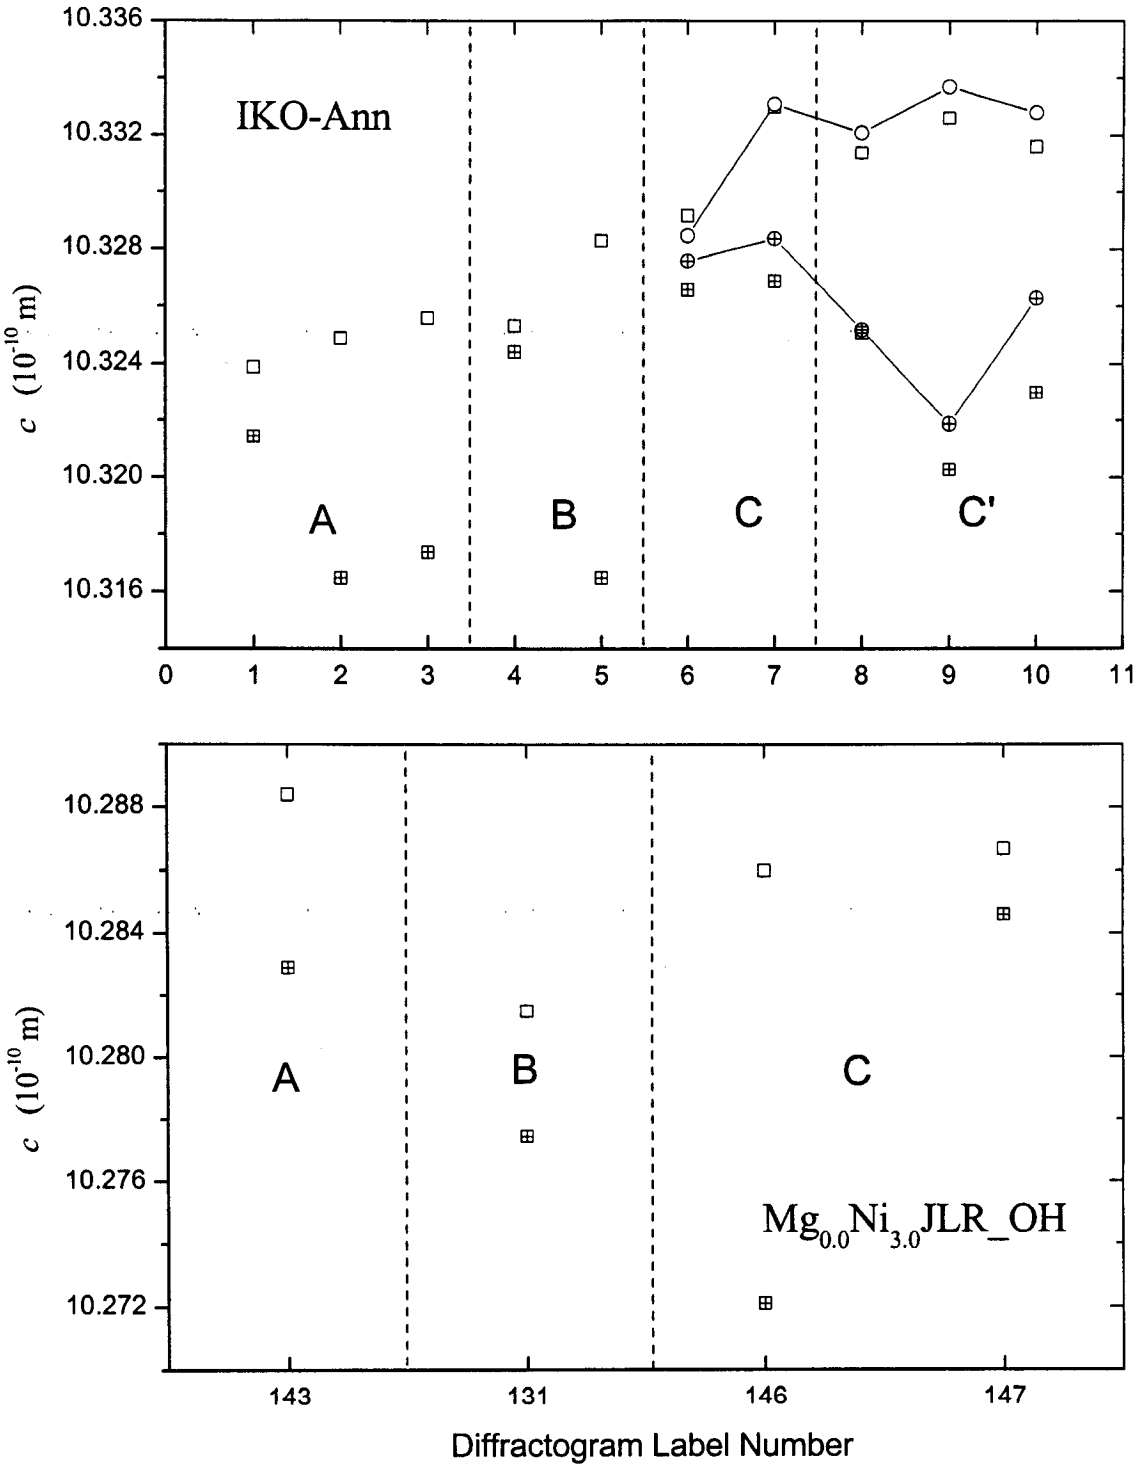

Figure 5.8. Values of lattice parameter c determined from various diffractograms of samples IKO-Ann (top) and $Ni_{3.0}$JLR (bottom) with $K\alpha_1$ positions evaluated by visual estimation (plus-squares) and FP fitting (open-squares).

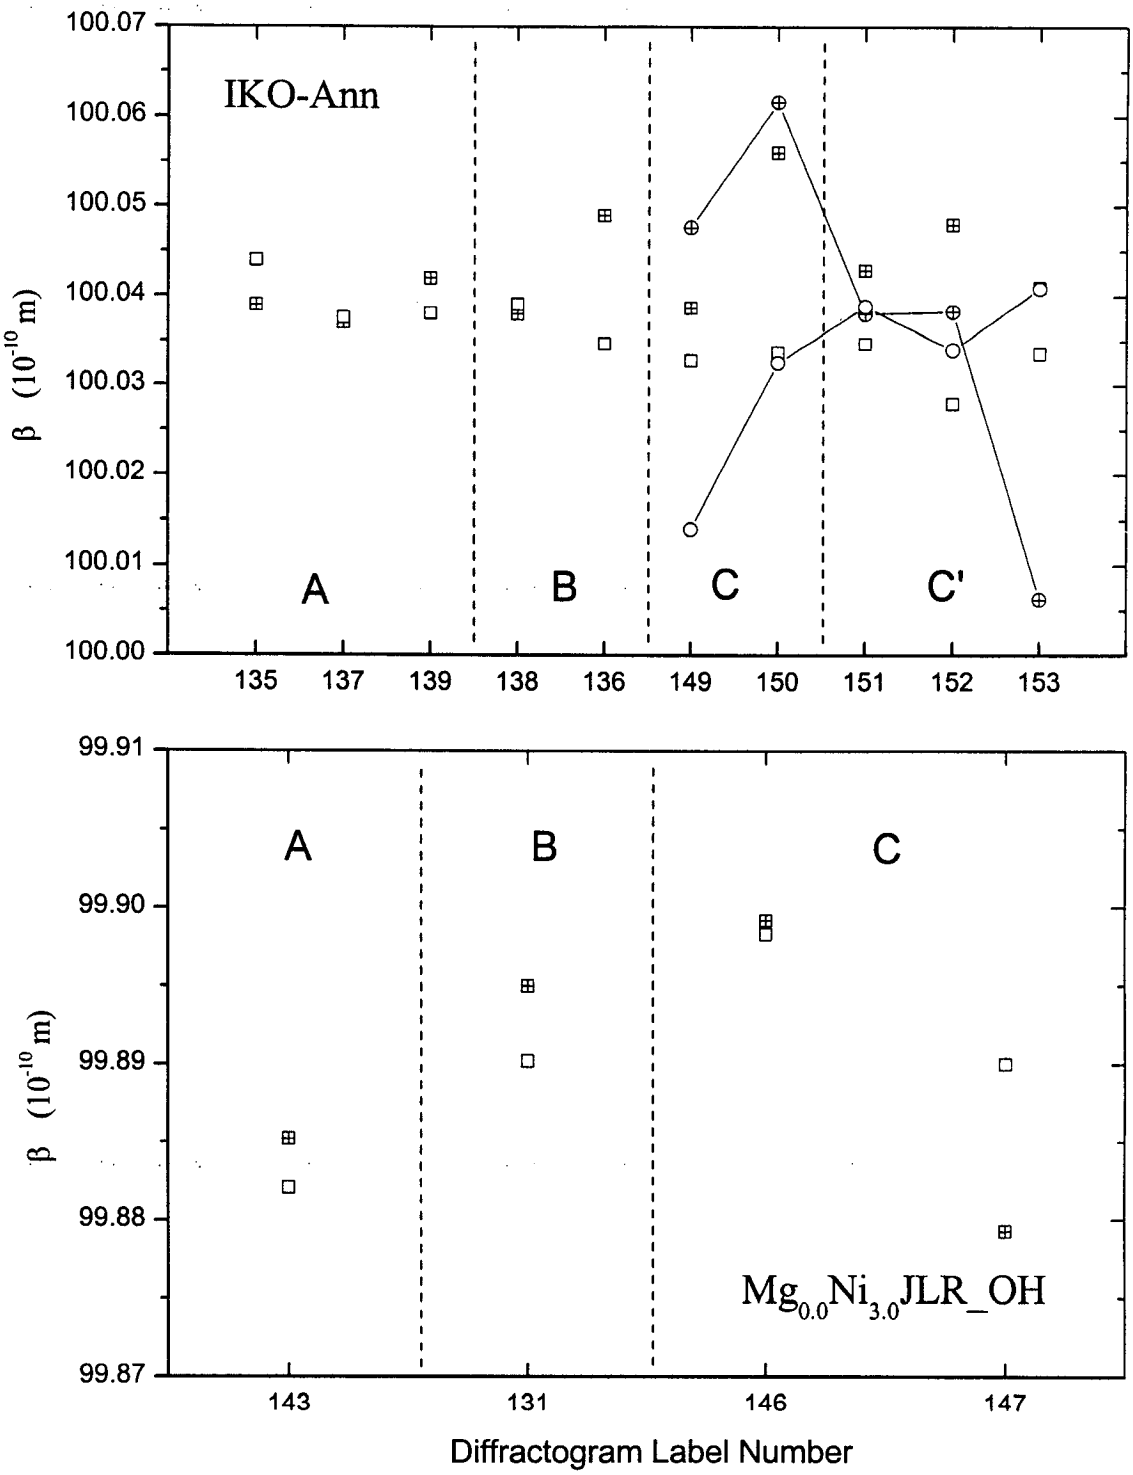

Figure 5.9. Values of lattice parameter β determined from various diffractograms of samples IKO-Ann (top) and $Ni_{3.0}$JLR (bottom) with $K\alpha_1$ positions evaluated by visual estimation (plus-squares) and FP fitting (open-squares).

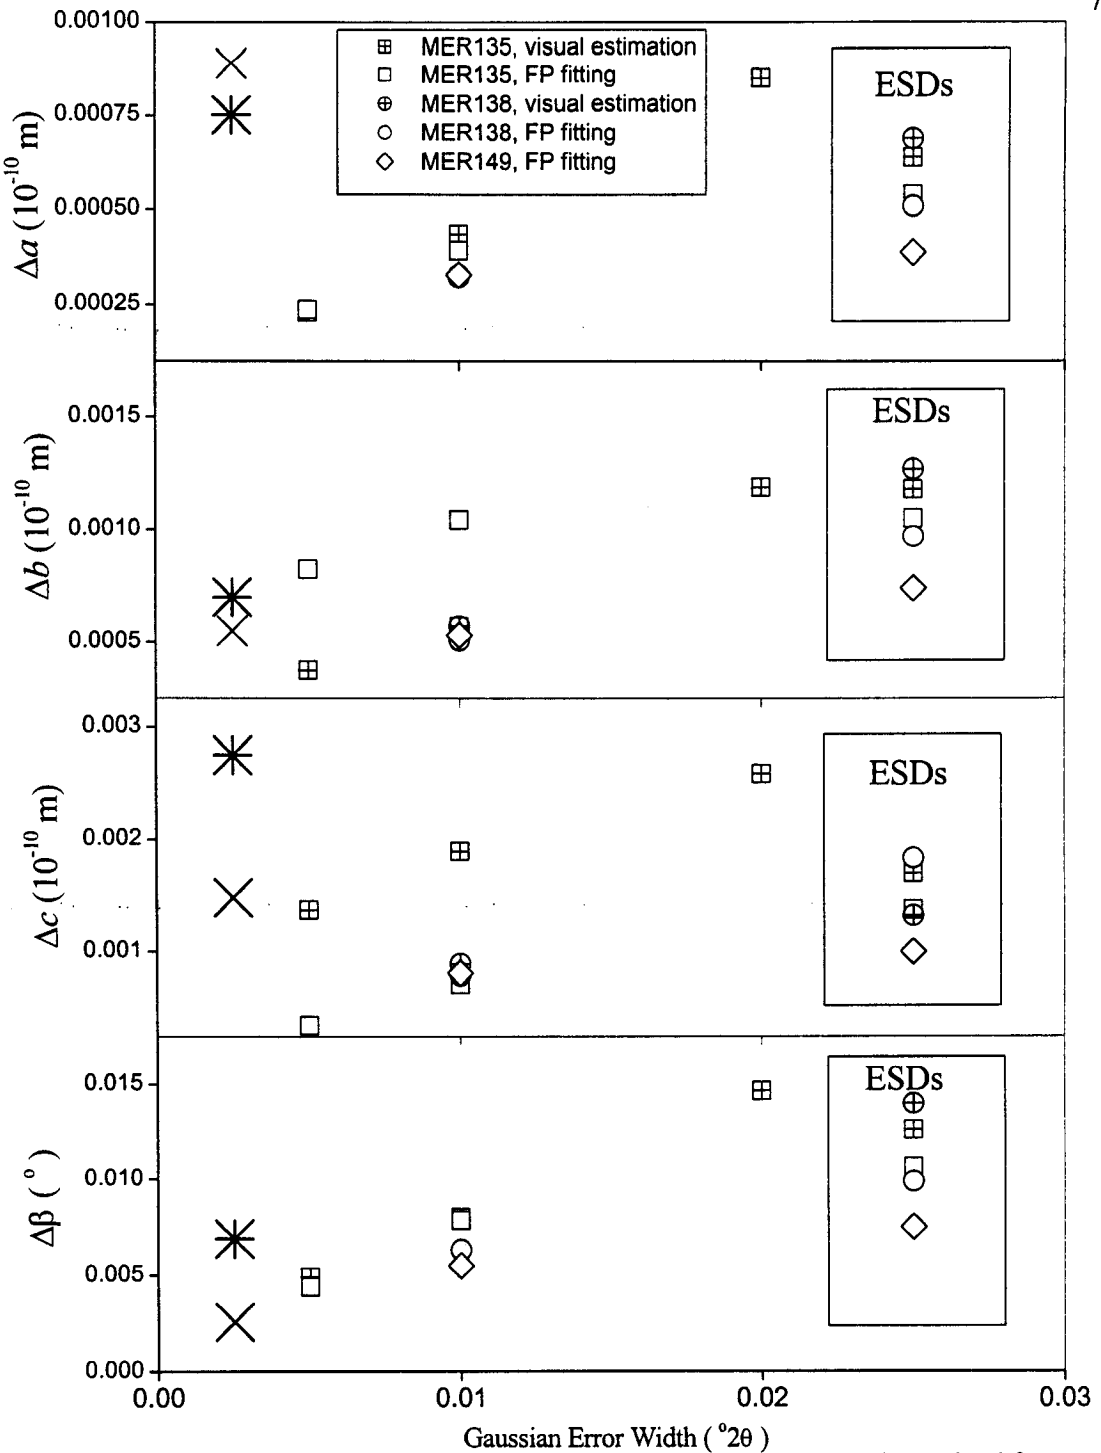

Figure 5.10. Comparison of : i) standard deviations of lattice parameters determined from diffractograms MER149 to MER153 by visual estimation (large stars) and FP fitting (large crosses), left; ii) standard deviations obtained by the synthetic method as a function of the assumed Gaussian error width, middle; and iii) ESDs output by CELREF, right.

5.2 Stacking polytype contents

Table 5.2 gives the results of structure factor calculations obtained for the $2M_1$, $2M_2$, $2O$, and $3T$ stacking polytypes using the fractional coordinates of Tables 4.2, 4.3, 4.4, and 4.5, respectively (see also Table 4.1). In these calculations, the same starting $1M$ unit cell as that of Table 5.1 was used — that is, the fractional coordinates of [Donnay *et al.*1964] with:
a = 5.3948 Å, b = 9.3440 Å, c = 10.3557 Å, β = 100°, d_o = 2.090 Å, and d_t = 1.680 Å.

In Table 5.2, the structure factor F^2_{hkl} values were divided by the squared volume of a given unit cell volume, V_c^2, as well as multiplied by the multiplicity of the reflection, m_{hkl}, to allow comparison between the different stacking polytypes. One notes that based on the presence or absence of a Bragg peak at a 2θ position corresponding to a given stacking polytype, one then has a clear set of criteria for the identification (and quantification, using our models) of mixtures of homogeneous stacking polytypes by powder X-ray diffraction. The criteria are in agreement with the accepted view that stacking polytype $3T$ cannot be distinguished from $1M$, whereas $2O$ is clearly recognizable if present in relatively large amounts.

Table 5.3 compiles the reflections of given sample observed at 2θ positions corresponding to other stacking polytypes than $1M$ (via the equations enumerated in Table 4.1) for various synthetic solid solution series. From these results, one concludes that the samples in Mg-Ni JLR and Co-Mg JLR series contain a mixture of stacking polytypes ($1M$, $2M_1$, and $2M_2$), whereas the other solid solution series appear to be nearly pure $1M$ stacking polytype samples.

Chapter 6. Testing of Geometrical Models

Simple geometrical models for the mica structure have been presented by [Pauling 1930], [Radoslovich 1961], [Donnay *et al.* 1964a], and [Takeda & Morosin 1975]. In the chronological order that they appeared, these are in fact a hierarchical sequence of modifications of one another; they are often referred to and used for various purposes (e.g., see [Hazen & Wones 1972; Takeda 1967; Takeda & Ross 1995; Nespolo *et al.* 1999; Mercier *et al.* 1996,1999; Rancourt *et al.* 2001]), as well as severely criticized [Weiss *et al.* 1985; Lin & Guggenheim 1983]. In this chapter we shall explore the limits of applicability of simple geometrical models, including those cited above and more sophisticated ones, in the prediction and interpretation of the crystal chemical properties of micas.

6.1 In-plane pseudo-hexagonal symmetry of mica layers

In layer silicates, the axes *a* and *b* are chosen to lie in a plane parallel to the layers, so that the *c* axis is the direction along which the layers stack one over another. The shortest distance connecting two *trans*-coordinated octahedral cations (*M1* sites) defines the *a* axis (Figure 6.1), whereas the *b* axis lies perpendicular to *a*. If the octahedral cations are arranged in a perfectly hexagonal pattern, then it can be shown that $b = \sqrt{3} \cdot a$.

Figures 6.2 and 6.3 show measured lattice parameters *b* as a function of *a* for synthetic samples reported in Section 5.2 and for single-crystal refinements of mica structures belonging to various stacking polytypes tabulated in Appendices P to T, inclusively. Both Figures 6.2 and 6.3 demonstrate that the straight line relationship $b = \sqrt{3} \cdot a$ is closely obeyed, except for a few structures of single-crystals that are discussed below. Such a relationship is not imposed by any of the known mica space groups corresponding to the different stacking polytypes, except for polytype $3T$ where it arises from the space group symmetry (trigonal). Note also that with stacking polytype $2M_2$, *a* and *b* are interchanged.

In the case of synthetic samples, it was found that the few exceptions where this relationship did not appear to hold could always be traced to an error in indexing one or more of the reflections or to an error in tabulating one or more of the peak positions. In practice, therefore, when dealing with synthetic *2:1* layer silicates, agreement with this relationship is valid evidence that a lattice parameter refinement has been done correctly.

Exceptions noted in Figure 6.3 can be explained as follows. Structure 1*M* No. 80 is the only known occurrence of norrishite, ideally $\{K^{1+}\}[Li^{1+}Mn^{3+}{}_2]\langle Si_4\rangle O_{12}$ [Tyrna & Guggenheim 1991]. The geometry of the *2:1* layer observed in this mineral is complicated due to three separate effects [Brigatti & Guggenheim 2002]: i) large displacement of octahedral *M2* cation, ii) elongation of octahedrons owing to Jahn-Teller effects, and iii) chemical ordering of Li^{1+} and Mn^{3+} on the *M1* and *M2* sites, respectively. Structure 2*O* No. 2 is an anandite specimen, ideally $\{Ba^{2+}\}[Fe^{2+}{}_3]\langle Si^{4+}{}_3Fe^{3+}\rangle O_{10}(OH)S$, which was refined in a symmetry reduced from *Ccmm* to *Pnmn* as a result of ordering of tetrahedral Fe^{3+} and Si, octahedral Fe and some Mg that is present, and the anions OH and S [Filut *et al.* 1985]. The remaining two anomalies are $2M_1$ structures. No. 26 is a crystal recovered by cooling after the dehydroxylation of a paragonite (ideally $\{Na^{1+}\}[Al^{3+}{}_2\square]\langle Si^{4+}{}_3Al^{3+}\rangle O_{10}(OH)_2$) specimen at 700 °C according to the reaction $2\ OH^- \rightarrow O^{2-} + H_2O\uparrow$ [Comodi & Zanazzi 2000]; after heat treatment, the composition is nominally $\{Na^{1+}\}[Al^{3+}{}_2\square]\langle Si^{4+}{}_3Al^{3+}\rangle O_{11}$ and an *M2* site with a near five-fold coordination is hence formed. Lastly, No. 33 is the structure of a lepidolite (Table 1.1) for which the refinement in *C2/c* symmetry indicated no tetrahedral ordering but ordering of octahedral cations so that *M1* = $Li_{0.93}[Mg,Mn,Fe]^{2+}{}_{0.06}Fe^{3+}{}_{0.01}$ and *M2* = $Al_{0.58}Li_{0.35}\square_{0.07}$; several tests were also performed which established that the true symmetry most likely is $C\bar{1}$ [Swan & Bailey 1981].

The $b = \sqrt{3} \cdot a$ relationship is a direct consequence of the hexagonal in-plane pseudo-symmetry of the mica layers, especially of the octahedral sheets. To the extent that this pseudo-symmetry is not broken by some features such as chemical order or peculiar site distortions, which were present for all exceptions pointed above, this relationship is expected to hold exactly.

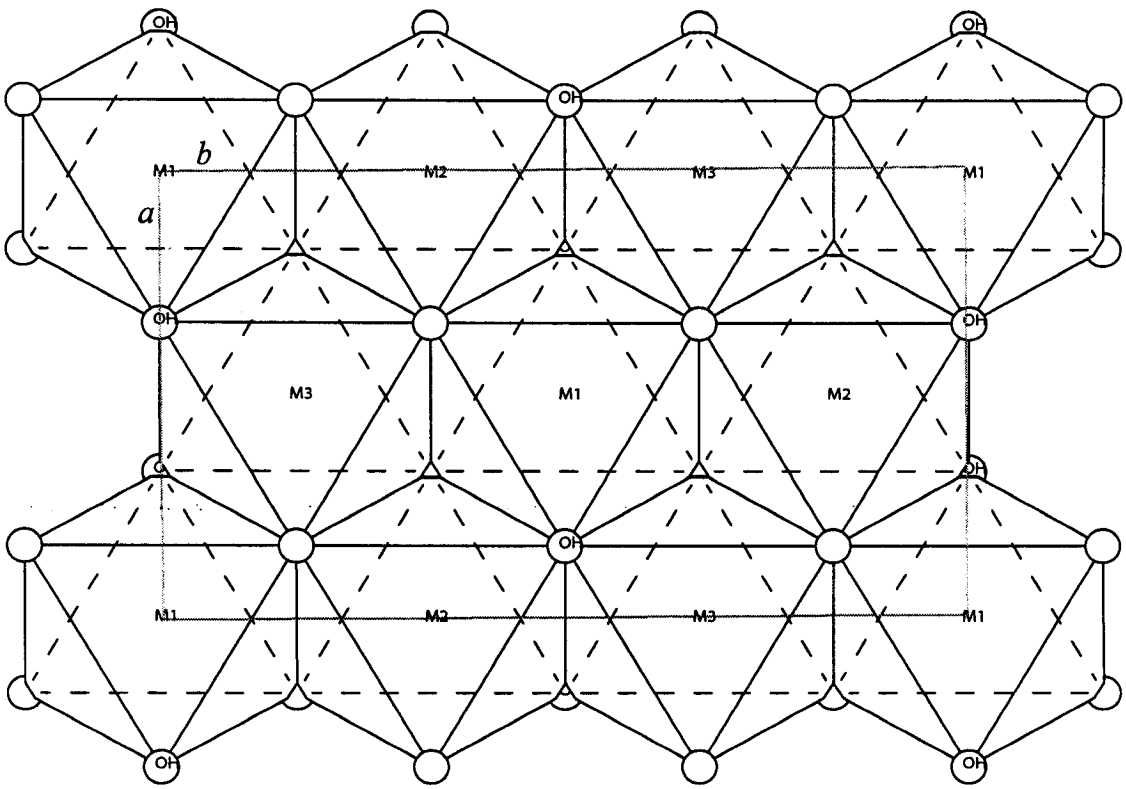

Figure 6.1. Diagram illustrating the *a* and *b* axes. *M*1 and *M*2/*M*3 symbols refer to octahedral cations that are *trans*- and *cis*- coordinated, respectively.

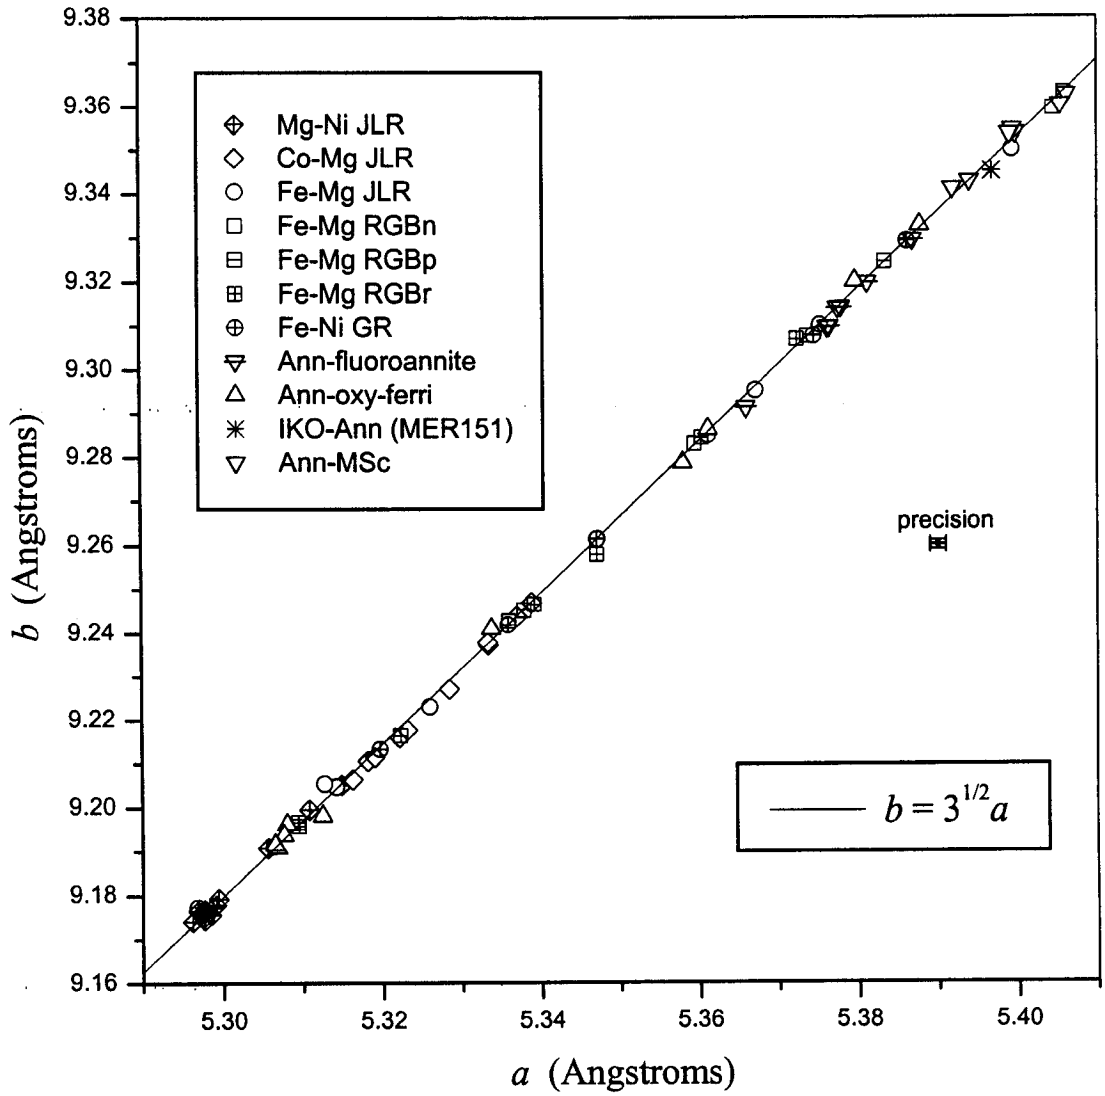

Figure 6.2. *b vs. a* for synthetic samples studied in this thesis. The labelled symbols indicated in the legend refer to the various sample solid solution series described in Table 3.1. The Ann-MSc symbol refers to the synthetic annite samples studied in [Mercier 1996].

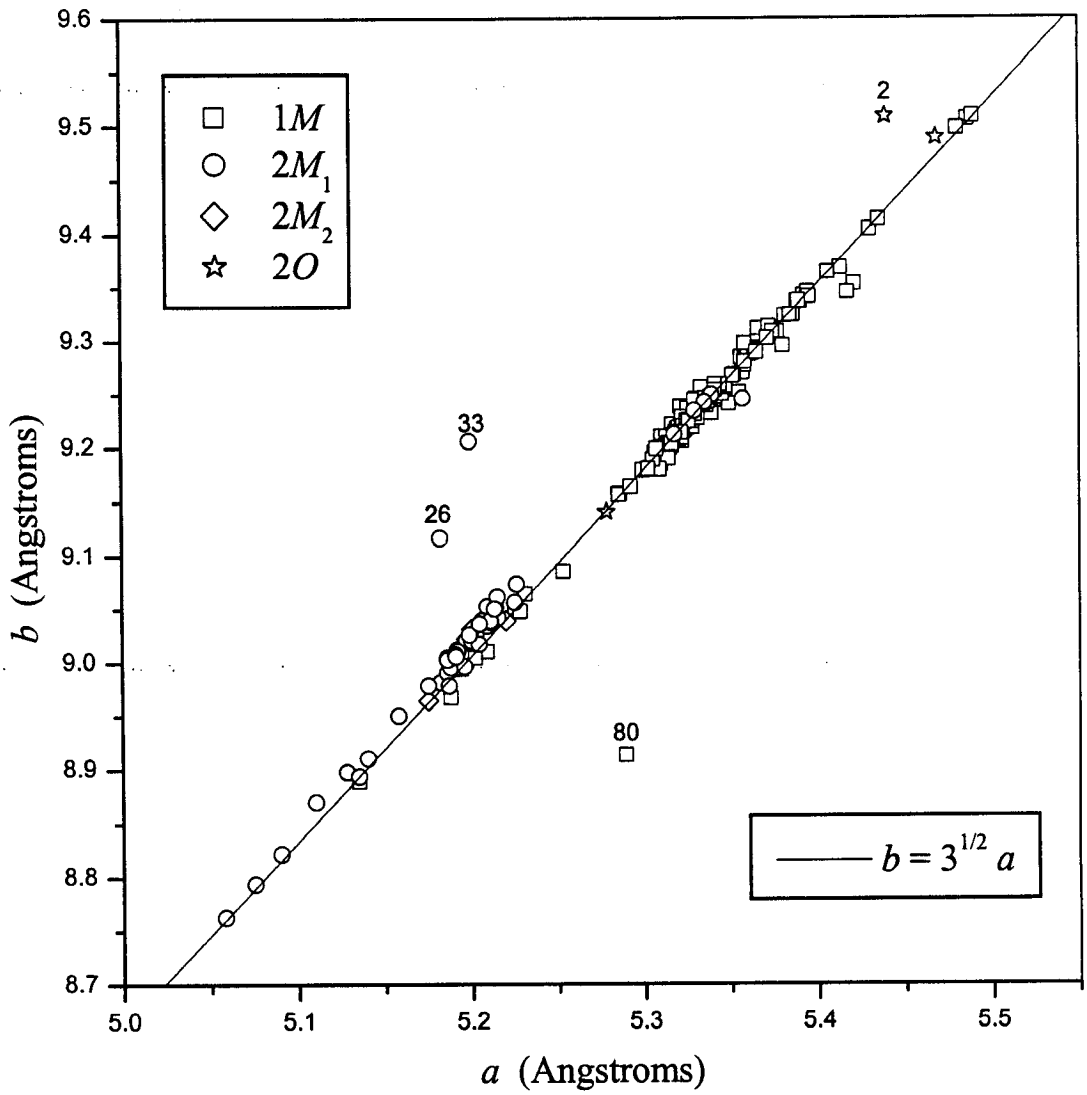

Figure 6.3. *b vs. a* for single-crystal structure refinements tabulated in Appendices P to T, inclusively. Notable exceptions are numbered with the corresponding structure No. given in the appropriate appendix. See text for a discussion of these anomalies.

6.2 Geometrical models

In Chapter 4, fractional atomic coordinates for each common stacking polytype were obtained by applying proper generating operations to a conventional 1*M* mica unit cell of space-group type *C*2/*m*. We will now present a hierarchy of progressively more realistic simple geometrical models of octahedrons and tetrahedrons, that will then be used to develop a crystal structure models for the 1*M* mica structure using idealized polyhedral networks.

6.2.1 An octahedron in an octahedral sheet

There are two distortions that preserve the bond length of an octahedron of a given height (Figure 6.4): i) iso-bond flattening, and ii) counter-rotation.

Iso-bond flattening is measured by the angle ψ between a line given by the direction of an octahedral bond length (*M-O*) and a line normal to the upper and lower triangular faces running through the central (octahedral) cation, *M*. If the height of an octahedron is decreased as a result of flattening alone (Figure 6.4b), then the upper and lower triangular faces are expanded (or vice-versa), maintaining their equilateral shape.

In an ideal octahedron (Figure 6.4a), the flattening angle is given by

(6.1) $$\psi_{ideal} = \arctan\left(\sqrt{2}\right) \cong 54.74^{\circ}.$$

As pointed out in [Donnay *et al.* 1964a], ψ_{ideal} is the cube-octahedron angle that can be read directly as the angle between the diagonal of a cube and the side edge contributing to the cosine of the angle. The following relationships also hold:

(6.2) $$\sin\psi_{ideal} = \sqrt{2/3} \quad ; \quad \cos\psi_{ideal} = \sqrt{1/3}\ .$$

The height of an octahedron, h_o, with bond length d_i and flattening ψ_i is given by:

(6.3) $$h_o = 2d_i \cos\psi_i .$$

As a consequence of flattening, the edges of an octahedron are no longer equal. The six unshared

edges that make up the upper and lower triangular faces are of length

(6.4) $$e_u^i = \sqrt{3} \cdot d_i \cdot \sin\psi_i$$

and the remaining six shared edges (i.e., shared with other octahedrons in the sheet) are of length

(6.5) $$e_s^i = d_i \sqrt{3 \cdot \cos^2\psi_i + 1} \quad .$$

It then follows that

(6.6) $$\left(\frac{e_s}{e_u}\right)_i = \sqrt{\frac{4}{\sin^2\psi_i} - 3} \qquad \text{or} \qquad \sin^2\psi_i = \frac{4}{3 \cdot \left[1 + \left(e_s/e_u\right)_i^2\right]} \quad ,$$

from which it can be obtained using Eqs. 6.1 to 6.6 that for an ideal octahedron:

(6.7) $$e_s^i = e_u^i = \sqrt{2} \cdot d_i \, .$$

Counter-rotation arises from rotating an octahedron's upper and lower triangular faces in opposite directions (Figure 6.4c). The counter-rotation angle, δ_i , is measured by the angle through which each triangular face is rotated. We will assume that if the rotation angle is positive, then the upper triangular face is rotated clockwise and the lower triangular face is rotated anti-clockwise.

As can be seen in Figure 6.4c, counter-rotation can be combined with iso-bond flattening. In this case the unshared edge lengths remain of the length given by Eq. 6.4, whereas the shared edges split into two groups of three, where the edge lengths of the two groups are:

(6.8a) $$e^{i}_{s+} = \sqrt{\left[2d_i \sin\psi_i \cos\left(60^o + \delta_i\right)\right] + h_o^2}$$ and

(6.8a) $$e^{i}_{s-} = \sqrt{\left[2d_i \sin\psi_i \cos\left(60^o - \delta_i\right)\right] + h_o^2}$$.

A demonstration that iso-bond flattening and counter-rotation together are enough to fit octahedrons of different sizes in a plane is made in [Evans 2001], where it is shown that one needs three different sized octahedral sites, each with a bond length d_i, a flattening ψ_i, and a counter-rotation δ_i, to make an octahedral sheet of uniform height h_o.

The flattening angles ψ_i of the three sites are determined from the three bond lengths d_i and the height of the octahedral sheet h_o as

(6.9) $$\frac{h_o}{2} = d_{M1}\cos\psi_{M1} = d_{M2}\cos\psi_{M2} = d_{M3}\cos\psi_{M3},$$

where $M1$, $M2$, and $M3$ designate each individual octahedral site.

Further, [Evans 2001] demonstrates that the following relations stem from fitting three different sized octahedrons of uniform height in a plane:

(6.10a)
$$\begin{aligned} d_{M1}\cos\left(60^\circ - \delta_{M1}\right)\sin\psi_{M1} &= d_{M2}\cos\left(60^\circ + \delta_{M2}\right)\sin\psi_{M2} \\ d_{M2}\cos\left(60^\circ - \delta_{M2}\right)\sin\psi_{M2} &= d_{M3}\cos\left(60^\circ + \delta_{M3}\right)\sin\psi_{M3} \\ d_{M3}\cos\left(60^\circ - \delta_{M3}\right)\sin\psi_{M3} &= d_{M1}\cos\left(60^\circ + \delta_{M1}\right)\sin\psi_{M1} \end{aligned}$$

and

(6.10b)
$$\begin{aligned} e_u^{M1}\cos\left(60^\circ - \delta_{M1}\right) &= e_u^{M2}\cos\left(60^\circ + \delta_{M2}\right) \\ e_u^{M2}\cos\left(60^\circ - \delta_{M2}\right) &= e_u^{M3}\cos\left(60^\circ + \delta_{M3}\right) \\ e_u^{M3}\cos\left(60^\circ - \delta_{M3}\right) &= e_u^{M1}\cos\left(60^\circ + \delta_{M1}\right) \end{aligned}$$

Despite the different sizes and shapes of the octahedrons in such a *geometric hetero-octahedral* sheet (following the nomenclature defined in Section 1.4), the cations are positioned in an ideal simple hexagonal lattice (this is also proven by [Evans 2001]).

Before we end this section, let us recall a few important points. Iso-bond flattening and counter-rotation do not alter the bond length of a given octahedron. This means that with only those two distortions acting, the *M-O* distance is equal to the *M-OH* distance in a given octahedron. The latter point is a rather important approximation, that will be discussed in Section 6.3 in the context of an overview of observed polyhedral distortions in 1*M* mica structures refined in space-group type *C*2/*m*.

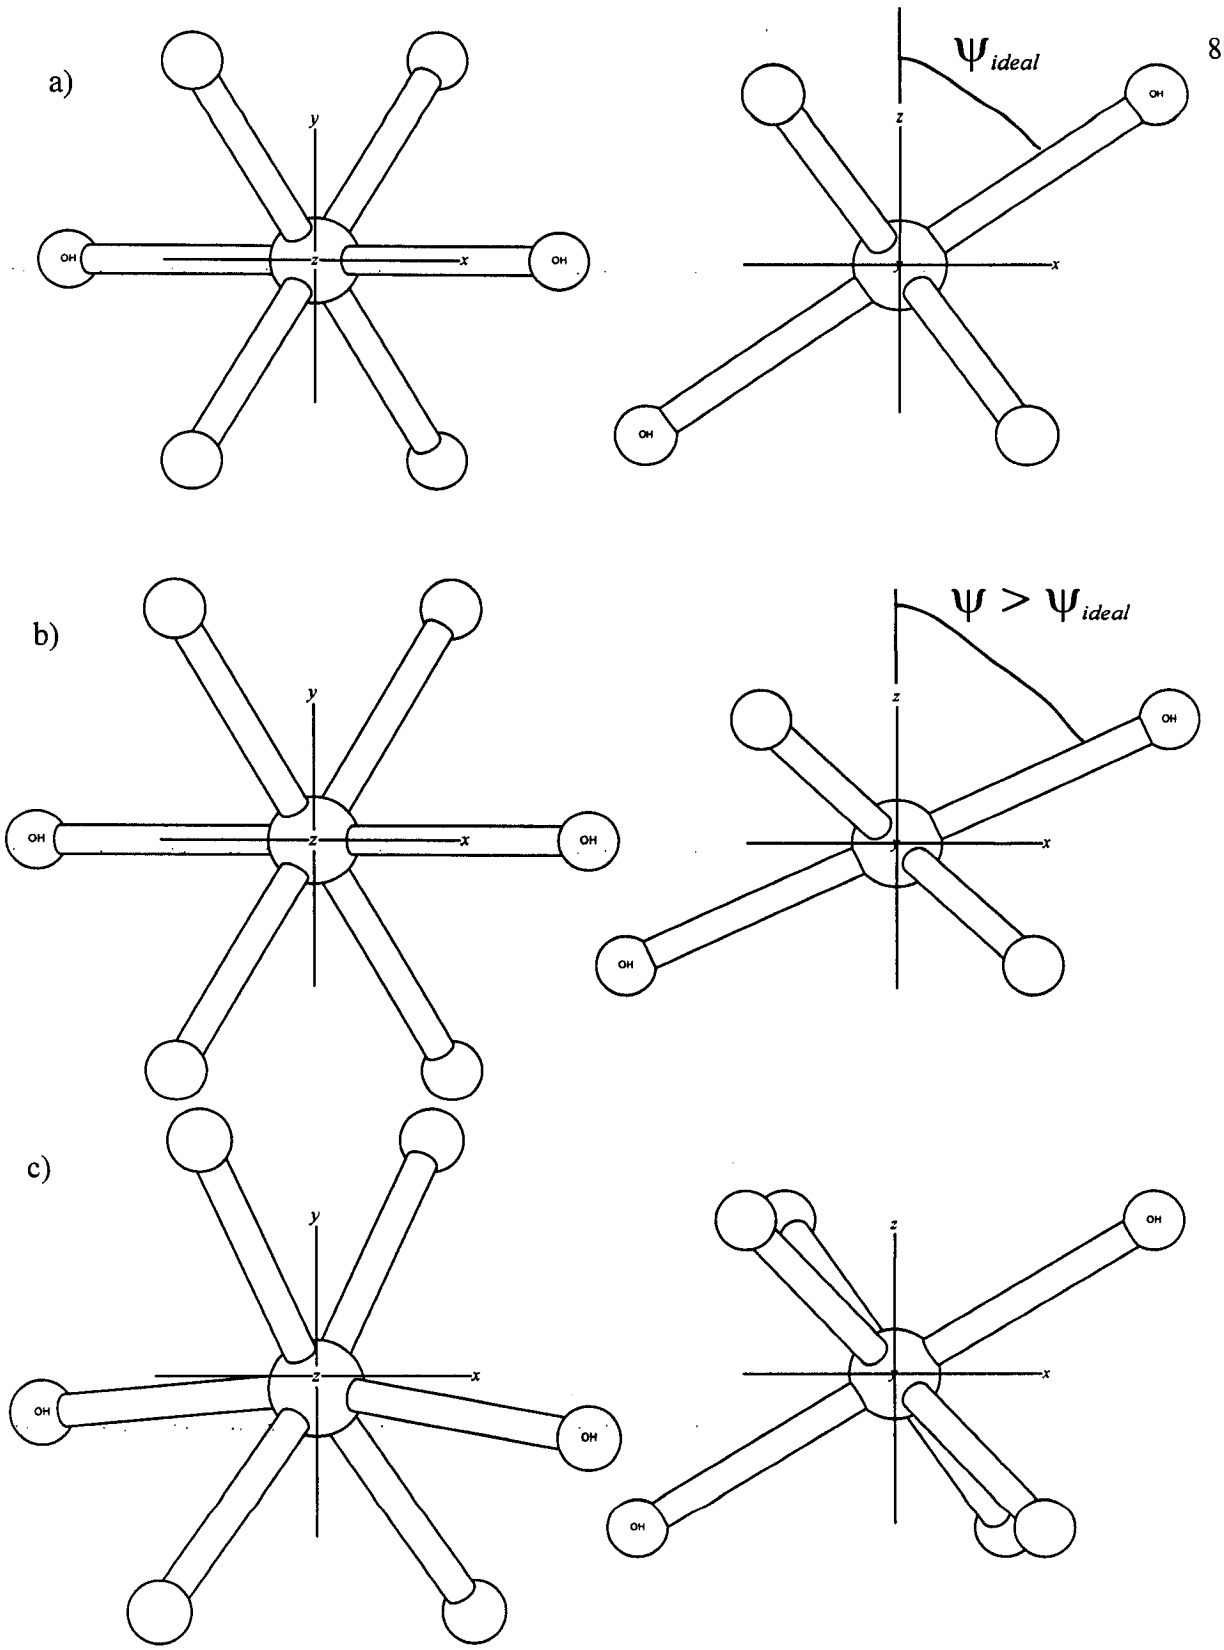

Figure 6.4. Geometrical models for an octahedron: a) ideal octahedron; b) iso-bond flattened octahedron; and c) iso-bond flattened and counter-rotated octahedron.

6.2.2 Geometric homo-octahedral sheet

From Eqns. 6.4, 6.9 and 6.10 it can be seen that if $d_{M1} = d_{M2} = d_{M3} = d_o$, then

$$\begin{aligned} \psi_{M1} = \psi_{M2} = \psi_{M3} = \psi \\ e_u^{M1} = e_u^{M2} = e_u^{M3} = e_u = \sqrt{3} \cdot d_o \cdot \sin\psi \\ \delta_{M1} = \delta_{M2} = \delta_{M3} = 0 \end{aligned} \tag{6.11}$$

Hence, when all bond lengths are equal, there is no counter-rotation, and iso-bond flattening is the only distortion that is applied uniformly to all octahedral sites. This type of octahedral sheet, which was first introduced by [Donnay *et al.* 1964a], is referred to as a *geometric homo-octahedral* sheet (following the nomenclature defined in Section 1.4).

In a geometric homo-octahedral sheet, the in-plane a and b lattice parameters can be expressed as (Figure 6.5):

$$\begin{aligned} a = 3 \cdot d_o \cdot \sin\psi = \sqrt{3} \cdot e_u \\ b = 3 \cdot \sqrt{3} \cdot d_o \cdot \sin\psi = 3 \cdot e_u \end{aligned} \tag{6.12}$$

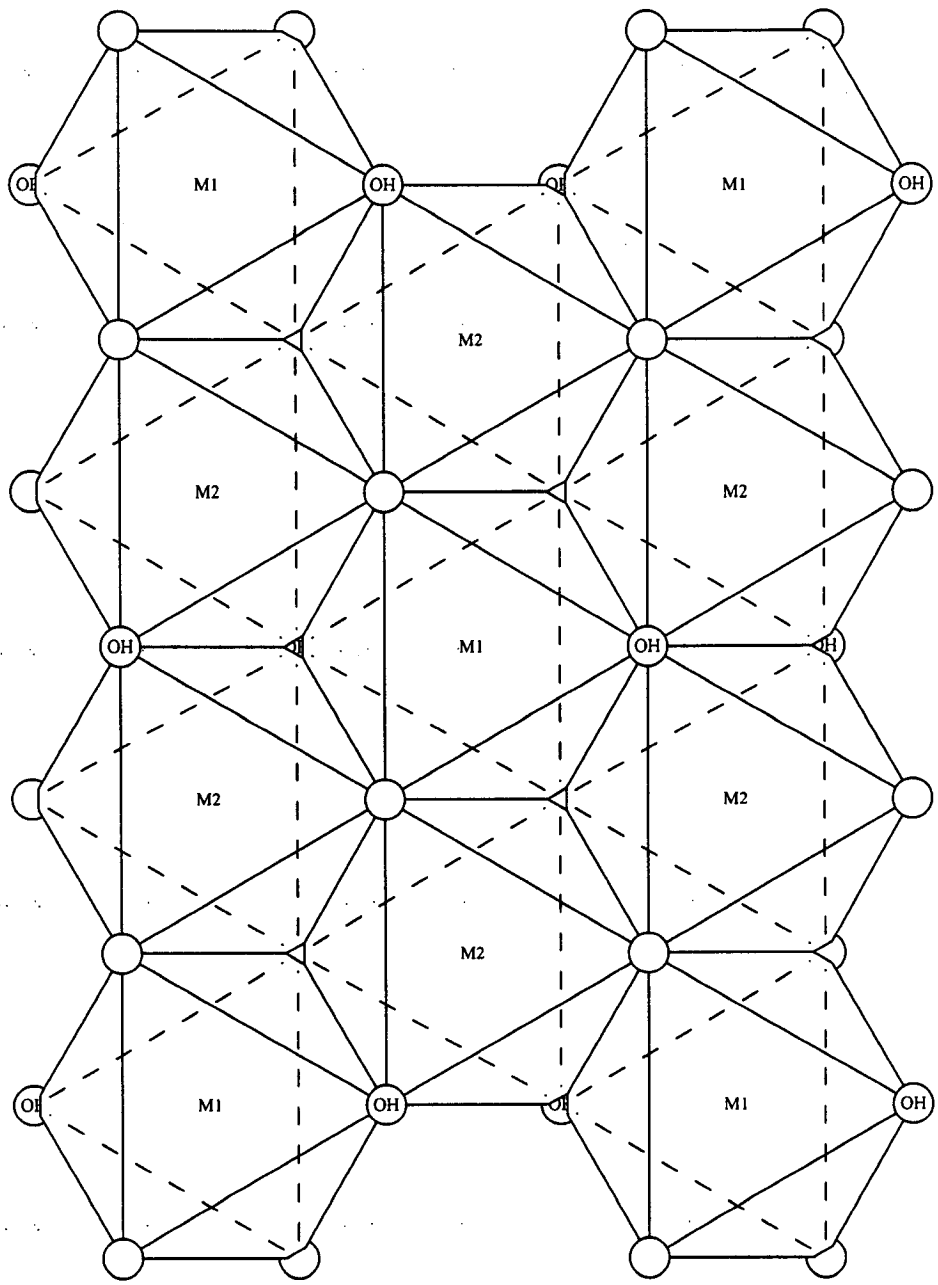

Figure 6.5. Geometrical model for a geometric homo-octahedral sheet.

6.2.3 Geometric meso-octahedral sheet

When only two bond lengths are equal, e.g. $d_{M1} \neq d_{M2} = d_{M3}$, then one finds (using Eqns. 6.4, 6.9, and 6.10):

$$\psi_{M1} \neq \psi_{M2} = \psi_{M3}$$
$$\delta_{M1} = 0 \quad , \quad \delta_{M2} = -\delta_{M3} \tag{6.13}$$

The two octahedrons with equal bond lengths and flattening angles have equal and opposite counter-rotation angles, whereas the distinct octahedral site has zero counter-rotation. This type of octahedral network is referred to as a *geometric meso-octahedral* sheet (Figure 6.6) following the nomenclature defined in Section 1.4.

From the results of [Evans 2001], it can be shown that:

$$a = 2 \cdot d_{M1} \sin\psi_{M1} + 2 \cdot d_{M2} \sin\psi_{M2} \sin\left(30° - \delta\right) = \frac{2}{\sqrt{3}}\left[e_u^{M1} + e_u^{M2} \sin\left(30° - \delta\right)\right]$$
$$b = \sqrt{3} \cdot d_{M1} \sin\psi_{M1} + 2 \cdot \sqrt{3} \cdot d_{M2} \sin\psi_{M2} \cos\delta = e_u^{M1} + 2 \cdot e_u^{M2} \cos\delta \tag{6.14}$$

In the latter equation, the notation was simplified in accordance with Eq. 6.12. If $\delta > 0$, then $d_{M1} > d_{M2}$; and vice-versa.

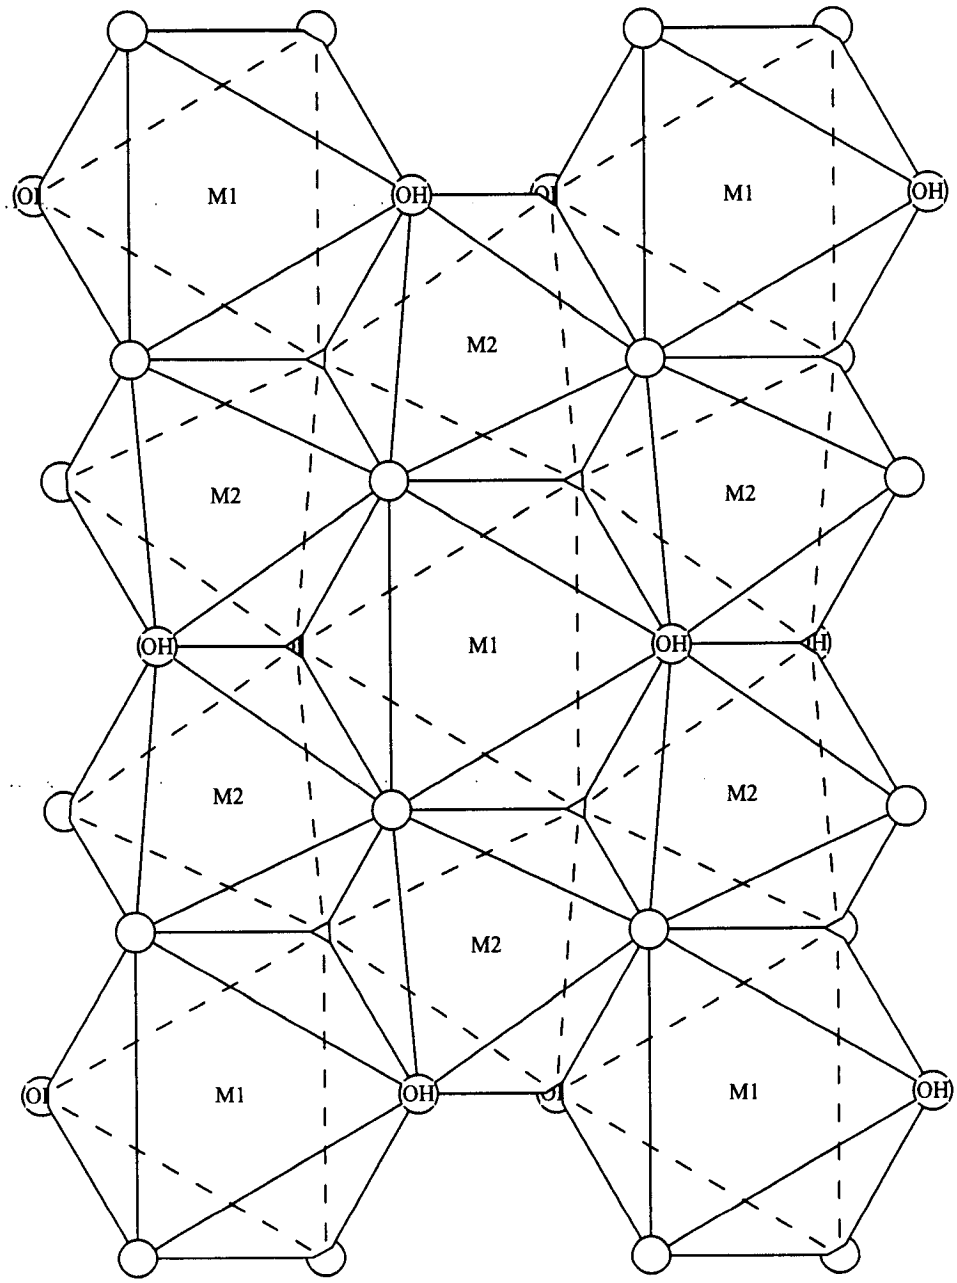

Figure 6.6. Geometrical model for a geometric meso-octahedral sheet.

6.2.4 A single tetrahedron

Consider the triangular pyramid displayed in Figure 6.7, which has the tetrahedral cation T as its summit and one basal oxygen atom, O_{bas}, for each corner of its base. If the O_{bas} atoms form an equilateral triangle of edge length e_t^{bas}, and T lies on a perpendicular through the centre of mass of the equilateral basal triangle, then the following relationships can be obtained from such a construction:

$$
\begin{aligned}
e_t^{bas} &= 2 \cdot d_t^{bas} \cdot \sin\left(\tau_{bas}/2\right) \\
h_t^{bas} &= d_t^{bas} \sqrt{1 - \frac{4}{3} \cdot \sin^2\left(\tau_{bas}/2\right)} \\
\varepsilon_{bas} &= \arccos\left[\frac{2}{\sqrt{3}} \sin\left(\tau_{bas}/2\right)\right]
\end{aligned}
\qquad (6.15)
$$

In the above expressions, the symbols have the following meanings: h_t^{bas} is the height of the pyramid; d_t^{bas} is the T-O_{bas} bond length; ε_{bas} is the angle that makes a T-O_{bas} bond with respect to the basal-oxygen plane; and τ_{bas} is the value of the three O_{bas}-T-O_{bas} angles.

One can construct various shapes of tetrahedrons using the above described pyramid as a building block. This approach is consistent with the shapes of actual tetrahedra in layer silicates, as will be shown below. If the apical oxygen atom O_{api} is placed on the same perpendicular through the basal equilateral triangle as T, then the following three types of tetrahedrons and their associated modes of distortion can be considered: i) the ideal tetrahedron (Figure 6.8); ii) iso-bond-basal-flattened tetrahedrons (Figure 6.9); and iii) aniso-bond tetrahedrons (Figure 6.10).

In an ideal tetrahedron (Figure 6.8) with tetrahedral bond length d_t and tetrahedral edge length e_t, one has

$$
\begin{aligned}
d_t &= d_t^{api} = d_t^{bas} \\
e_t &= e_t^{bas} = e_t^{api} = 2 \cdot \sqrt{2/3} \cdot d_t \\
\tau_{bas} &= \tau_{api} = \tau_{ideal} = 2 \cdot \psi_{ideal} \cong 109.47^\circ \\
\varepsilon_{bas} &= 2 \cdot \psi_{ideal} - 90^\circ \\
h_t &= h_t^{bas} + d_t = 4/3 \cdot d_t
\end{aligned}
\qquad (6.16)
$$

where: d_t^{api} is the length of the T-O_{api} bond; e_t^{api} is the length of the three O_{api}-O_{bas} lateral edges; τ_{api} is value of the three O_{api}-T-O_{bas} angles; ψ_{ideal} is the cube-octahedron angle described by Eqns. 6.1 and 6.2; and h_t is the height of the tetrahedron. There are no distortion in an ideal tetrahedron: all T-O bonds have the same length and all O-T-O angles are the same.

In iso-bond-basal-flattened tetrahedrons (Figure 6.9) all T-O bond lengths are equal but the τ_{bas} angle is allowed to vary — hence the 'iso-bond-basal-flattened' label ('iso-bond' for short). The relationships characterizing an iso-bond tetrahedron can be written as

$$\begin{aligned} d_t &= d_t^{bas} = d_t^{api} \\ h_t &= d_t + h_t^{bas} \\ e_t^{api} &= \sqrt{h_t^2 + 1/3 \cdot \left(e_t^{bas}\right)^2} \\ \tau_{api} &= 90^\circ + \varepsilon_{bas} \end{aligned} \quad , \tag{6.17}$$

where h_t^{bas}, e_t^{bas}, and ε_{bas} are given by Eq. 6.15. Hence, it can be seen that an iso-bond tetrahedron is fully defined by specifying its bond length d_t and one other parameter. An iso-bond tetrahedron has two 'degrees of freedom'. This geometrical model of a tetrahedron was first presented by [Takeda & Morosin 1975].

In the case of an aniso-bond tetrahedron (Figure 6.10), the T-O_{api} bond length is not equal to the T-O_{bas} bond length — hence the 'aniso-bond' label. The relationships describing an aniso-bond tetrahedron can then be expressed as

$$\begin{aligned} d_t^{bas} &\neq d_t^{api} \\ h_t &= d_t^{api} + h_t^{bas} \\ e_t^{api} &= \sqrt{h_t^2 + 1/3 \cdot \left(e_t^{bas}\right)^2} \\ \tau_{api} &= 90^\circ + \varepsilon_{bas} \end{aligned} \quad , \tag{6.18}$$

where h_t^{bas}, e_t^{bas}, and ε_{bas} are also given by Eq. 6.15. An aniso-bond tetrahedron described Eq. 6.18 has three degrees of freedom: d_t^{bas} and d_t^{api}, and one other parameter. We are the first to consider aniso-bond tetrahedra in simple geometrical models of layer silicates.

6.2.5 Tetrahedral sheet

In layer silicates, tetrahedrons are linked together by sharing basal oxygen atoms as shown in Figure 6.11. If the following assumptions are made:

i) the basal oxygen atoms in each tetrahedral sheet are coplanar and their plane orientation in (001);
ii) the basal faces of tetrahedrons are equilateral triangles articulated at their vertices (Figure 6.11); and
iii) the orthohexagonal relationship $b = \sqrt{3} \cdot a$ is rigorously obeyed;

then [Donnay *et al.* 1964b] have shown that by rotating each tetrahedron by an angle α about an axis perpendicular to the (001) plane, the lateral size of the tetrahedral sheet is reduced.

In terms of the tetrahedral rotation angle α and the basal edge length e_t^{bas} of the equilateral faces, it follows that the in-plane *a* and *b* lattice parameters are given by

$$a = 2 \cdot e_t^{bas} \cdot \cos \alpha$$
$$b = 2 \cdot \sqrt{3} \cdot e_t^{bas} \cdot \cos \alpha \qquad (6.19)$$

Tetrahedral sheet models having ideal tetrahedra with $\alpha = 0°$ and $\alpha \neq 0°$ are referred to as the *Pauling model* and the *Trigonal model*, respectively (e.g., [Nespolo 1999; Ferraris & Vivaldi 2002]).

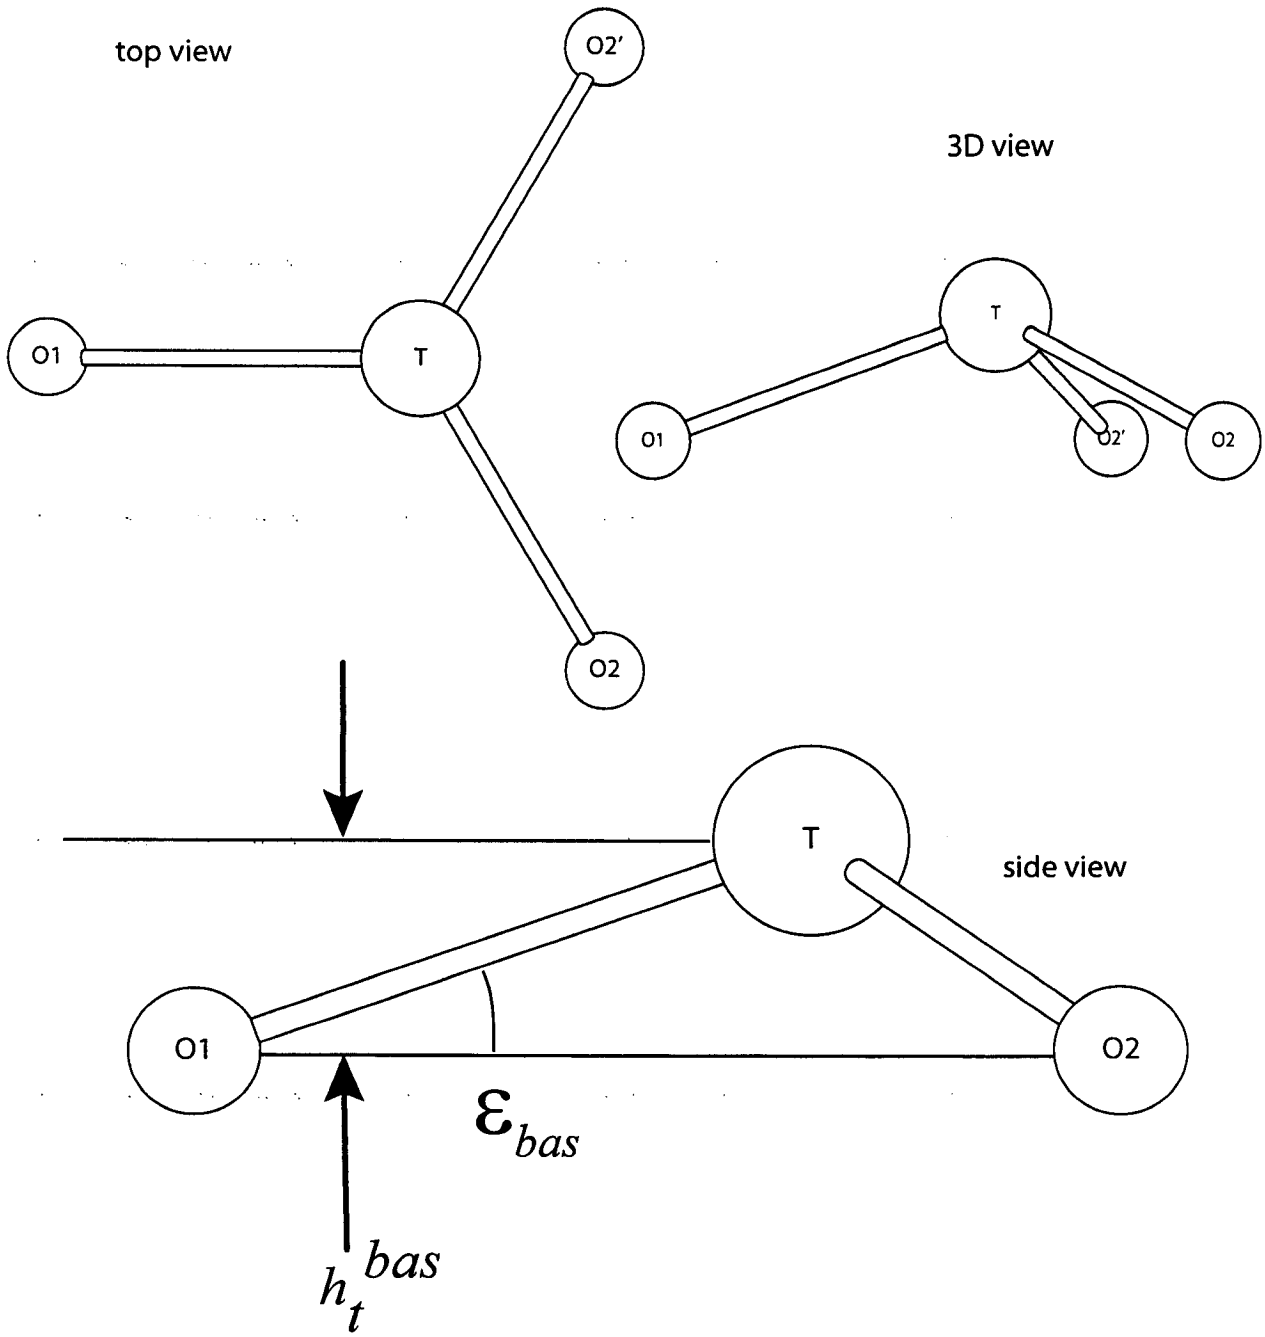

Figure 6.7. Pyramid formed by the tetrahedral cation *T* and the three basal oxygen atoms (denoted O1, O2, and O2'). The various symbols that are shown are explained in the text.

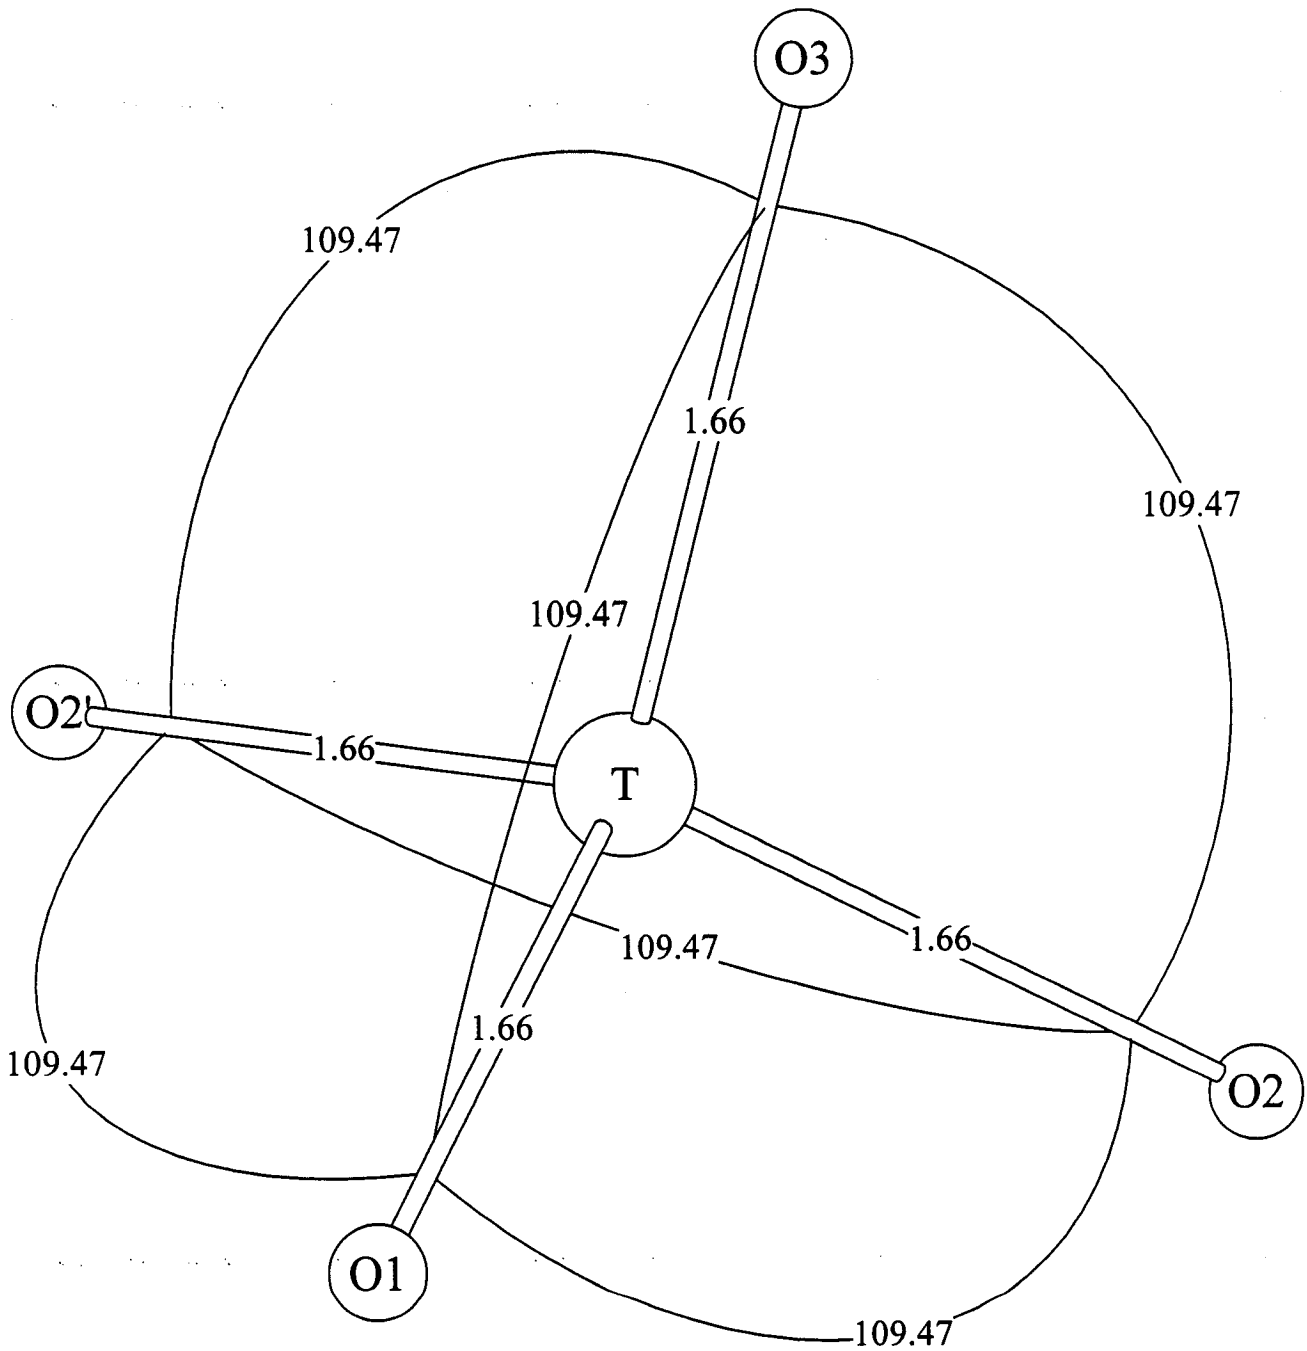

Figure 6.8. An ideal tetrahedron. The tetrahedral cation *T* is equidistant from the three basal oxygen atoms (denoted O1, O2, and O2') and the apical oxygen atom (O3), and all O-T-O angles have the same value (~109.47°).

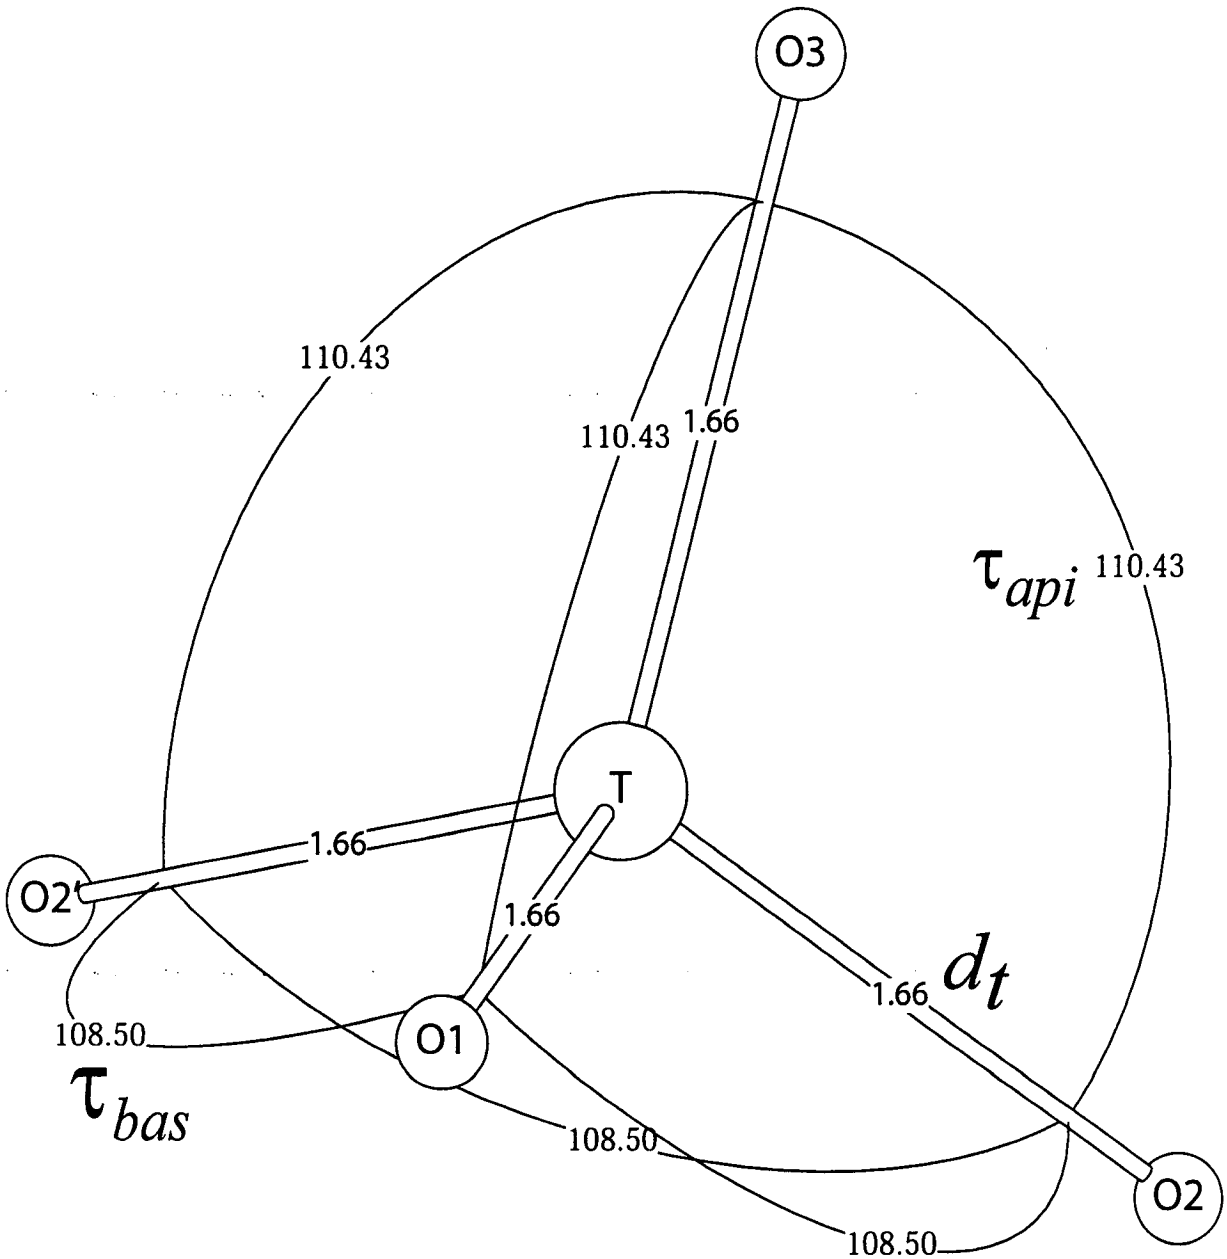

Figure 6.9. An iso-bond-basal-flattened tetrahedron (iso-bond tetrahedron for short). The tetrahedral cation *T* is equidistant from the three basal oxygen atoms (denoted O1, O2, and O2') and the apical oxygen atom (O3), but the value of the three O_{bas}-*T*-O_{bas} angles is allowed to vary.

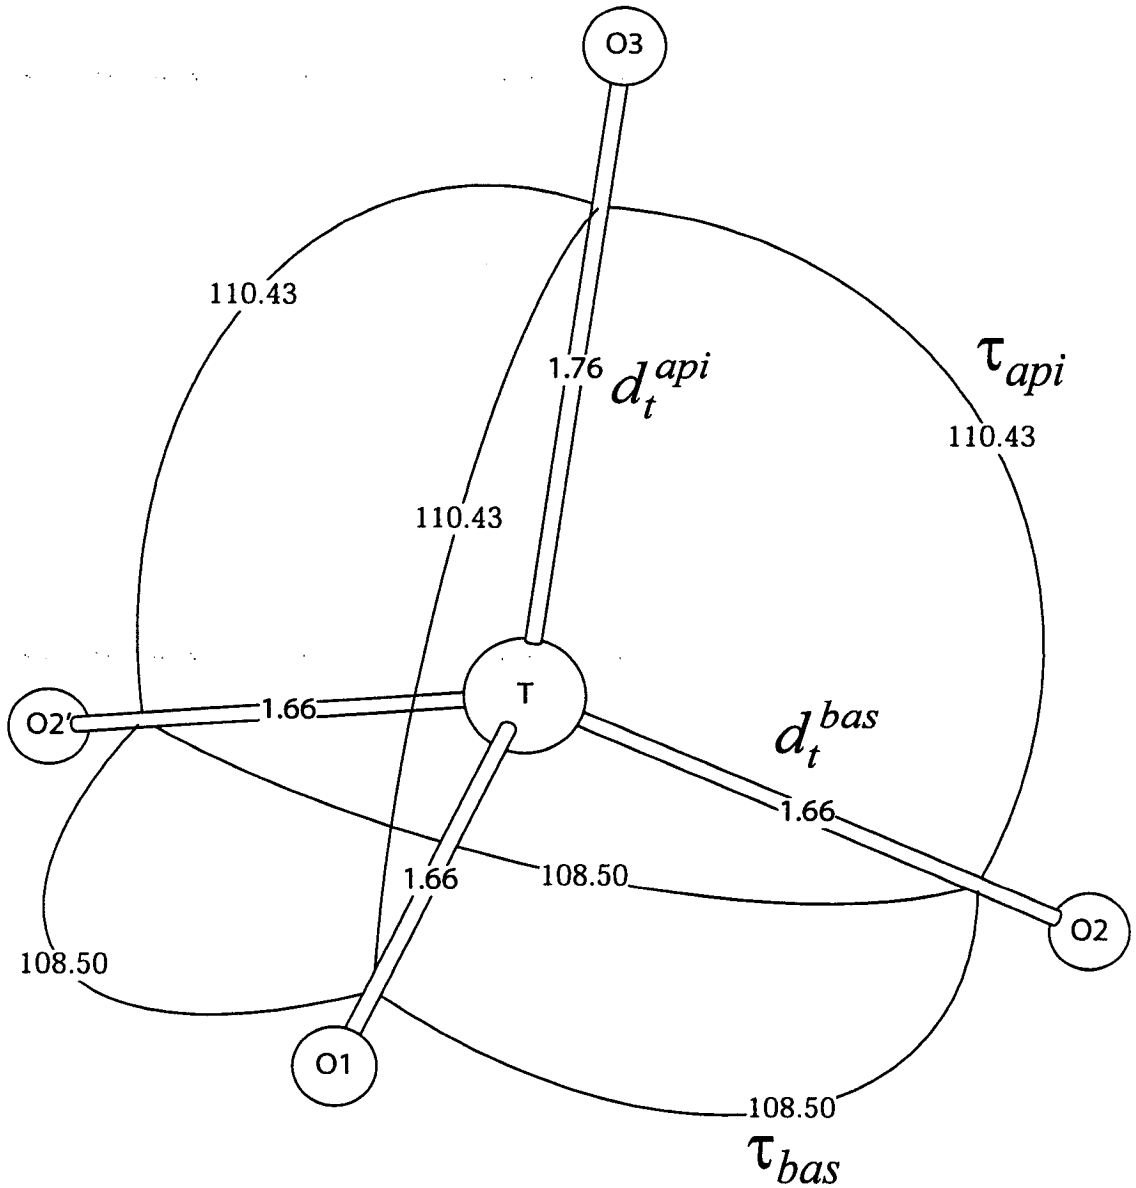

Figure 6.10. An aniso-bond tetrahedron. The distance between tetrahedral cation *T* and the one of the three basal oxygen atoms (denoted O1, O2, and O2') is different from the distance between *T* and the the apical oxygen atom (O3), and the value of the three O_{bas}-*T*-O_{bas} angles is allowed to vary.

6.2.6 Crystal structure model for a 1*M* mica unit layer

It is now possible to construct a complete crystal structure model using idealized polyhedral networks. Consider a geometric homo-octahedral sheet to which is attached two tetrahedral sheets via the apical oxygen atoms, one above and another below, that are comprised of tetrahedrons that have their equilateral triangular basal faces lying in two single planes whose orientation is parallel to the plane of octahedral cations (Figure 6.12).

Suppose the interlayer cations lie directly above and below the OH/F groups on perpendiculars through to the *a*-*b* plane, which also go through the geometric centres of the hexagons formed by: i) the lower and upper tetrahedral apical oxygen atoms; ii) the lower and upper tetrahedral cations; and iii) the lower and upper tetrahedral basal oxygen atoms. Then, in the case of such an idealized homo-octahedral network, it can be seen (Figure 6.12) that the projections in the *a*-*b* plane of the sides of the hexagons formed by the apical oxygen atoms and tetrahedral cations are superimposed one over another, and their length is equal to *b*/3. The basal edge length of the equilateral triangular faces is related to the *a* and *b* lattice parameters via Eq. 6.19.

One now needs to define the *c* and β lattice parameters (Figure 6.13). The *c*-axis has a length equal to the norm of the shortest vector linking an interlayer cation lying below the octahedral and lower tetrahedral sheets on one end, to another interlayer cation located above the octahedral and upper tetrahedral sheets on the other end. For the conventional 1*M* mica unit layer, the origin of the unit cell is chosen so that the interlayer and *trans*-octahedral cations occupy special symmetry positions 2*b* and 2*c* of space-group type *C*2/*m* (space-group type No. 12; first setting), respectively [Pabst 1955; Donnay *et al.* 1964a, 1964b].

In the case on an idealized geometric homo-octahedral network as described above, it can be demonstrated that the projection of the *c*-axis on the *a*-*b* plane is

$$c \cdot \cos\beta^* = \frac{a}{3}, \tag{6.20}$$

where $\beta^* = \left(180^\circ - \beta\right)$. The vector that consists of this projection is illustrated on Figures 6.12 and 6.13, and is referred to as the interlayer stacking vector. The in-plane axes corresponding to the conventional 1*M* unit layer, a_{1M} and b_{1M}, are also indicated.

One can easily notice on Figure 6.13 that the interlayer spacing, d_{int}, is related to *c* by

$$c^2 = \frac{a^2}{9} + \left[d_{int} + h_o + 2 \cdot h_t\right]^2 \quad , \tag{6.21}$$

where h_o and h_t are the heights octahedral and tetrahedral sheets, respectively.

Let us now focus on the geometry of the interlayer site (Figure 6.14). As a result of tetrahedral rotation, one observes that the basal oxygen atoms form 'inner' and 'outer' octahedrons around each interlayer cation *A*. In terms of the basal edge length e_t^{bas} and the tetrahedral rotation angle α, the inner and outer bond lengths of the interlayer site can be written as [Takeda & Morosin 1975]:

$$\left(A-O\right)_{in}{}^2 = \nu^2 + \left\{e_t^{bas} - e_t^{bas}\left[\frac{\sqrt{3}}{3}\sin\alpha + \left(1-\cos\alpha\right)\right]\right\}^2$$

$$\left(A-O\right)_{out}{}^2 = \nu^2 + \left\{e_t^{bas} + e_t^{bas}\left[\frac{\sqrt{3}}{3}\sin\alpha - \left(1-\cos\alpha\right)\right]\right\}^2 \tag{6.22}$$

where

$$\nu = 1/2 \cdot \left[c \cdot \sin\beta - h_o - 2 \cdot h_t\right] \quad . \tag{6.23}$$

The subscripts 'in' and 'out' denote the inner and outer octahedrons, respectively.

Noting that the inner and outer interlayer octahedrons hence built are flattened but not counter-rotated, one can then define flattening angles for each of these octahedrons, which are referred to as ϕ_{in} and ϕ_{out}. The inner and outer interlayer octahedrons have a height equal to the interlayer spacing d_{int}; the orientations of their lower and upper triangular faces are opposite from one to another. The relationships giving ϕ_{in} and ϕ_{out} are simply

$$\cos\phi_{in} = \frac{d_{int}/2}{\left(A-O\right)_{in}}$$

$$\cos\phi_{out} = \frac{d_{int}/2}{\left(A-O\right)_{out}} \quad , \tag{6.24}$$

where $\left(A-O\right)_{in}$ and $\left(A-O\right)_{out}$ are given by Eq. 6.21.

The interlayer spacing d_{int} can be expressed as a function of the lattice parameter a, the tetrahedral rotation α, and the inner interlayer $(A-O)_{in}$ as (following [Franzini & Schiaffino 1963]):

(6.25a) $$d_{int} = \sqrt{4\cdot(A-O)_{in}{}^2 - a^2\left[1-\frac{\sqrt{3}}{3}\cdot\tan\alpha\right]^2}$$

(6.25b) $$d_{\text{int}} = \sqrt{4\cdot(A-O)_{in}{}^2 - 4\left(e_t^{bas}\right)^2\left[\cos\alpha - \frac{1}{\sqrt{3}}\sin\alpha\right]^2}$$.

We now have a complete set of equations that can be used to specify the coordinates of all atoms in a 1*M* mica unit layer comprised of a geometric homo-octahedral sheet, that depend on the particular shapes assumed for the tetrahedrons. Table 6.1 summarizes the characteristics of the different models presented in this section.

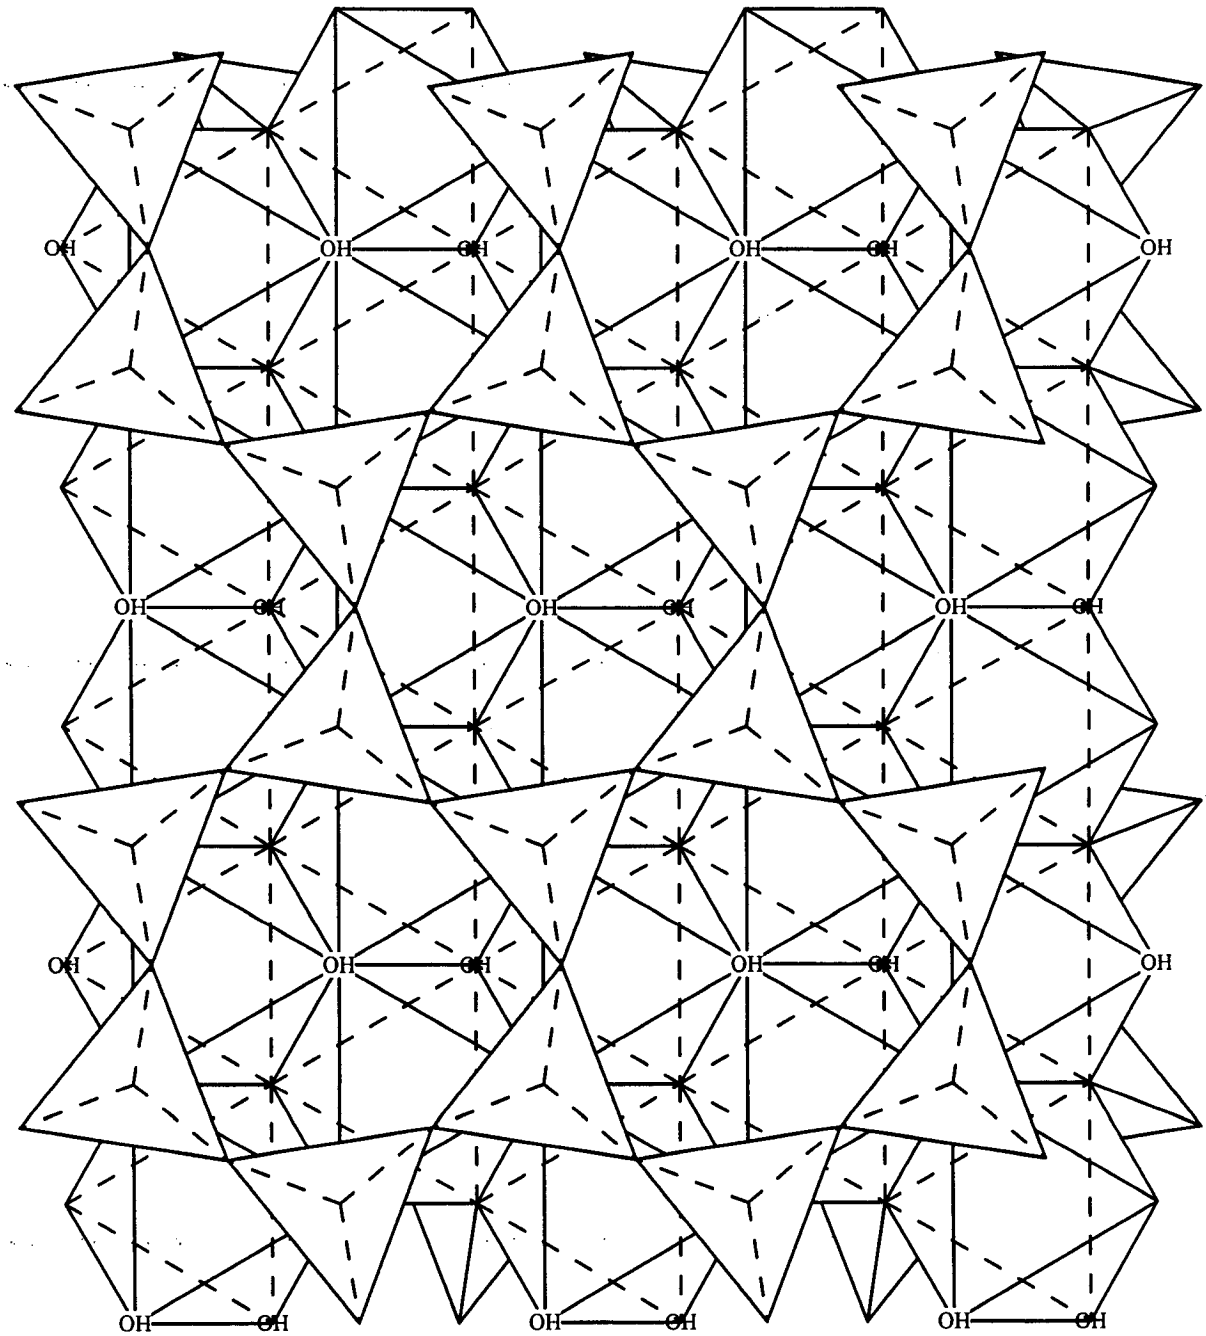

Figure 6.12. Crystal structure model for a geometric homo-octahedral sheet to which is attached two tetrahedral sheets via the apical oxygen atoms. The interlayer cations are placed directly above the OH/F groups on a perpendicular to the *a-b* plane.

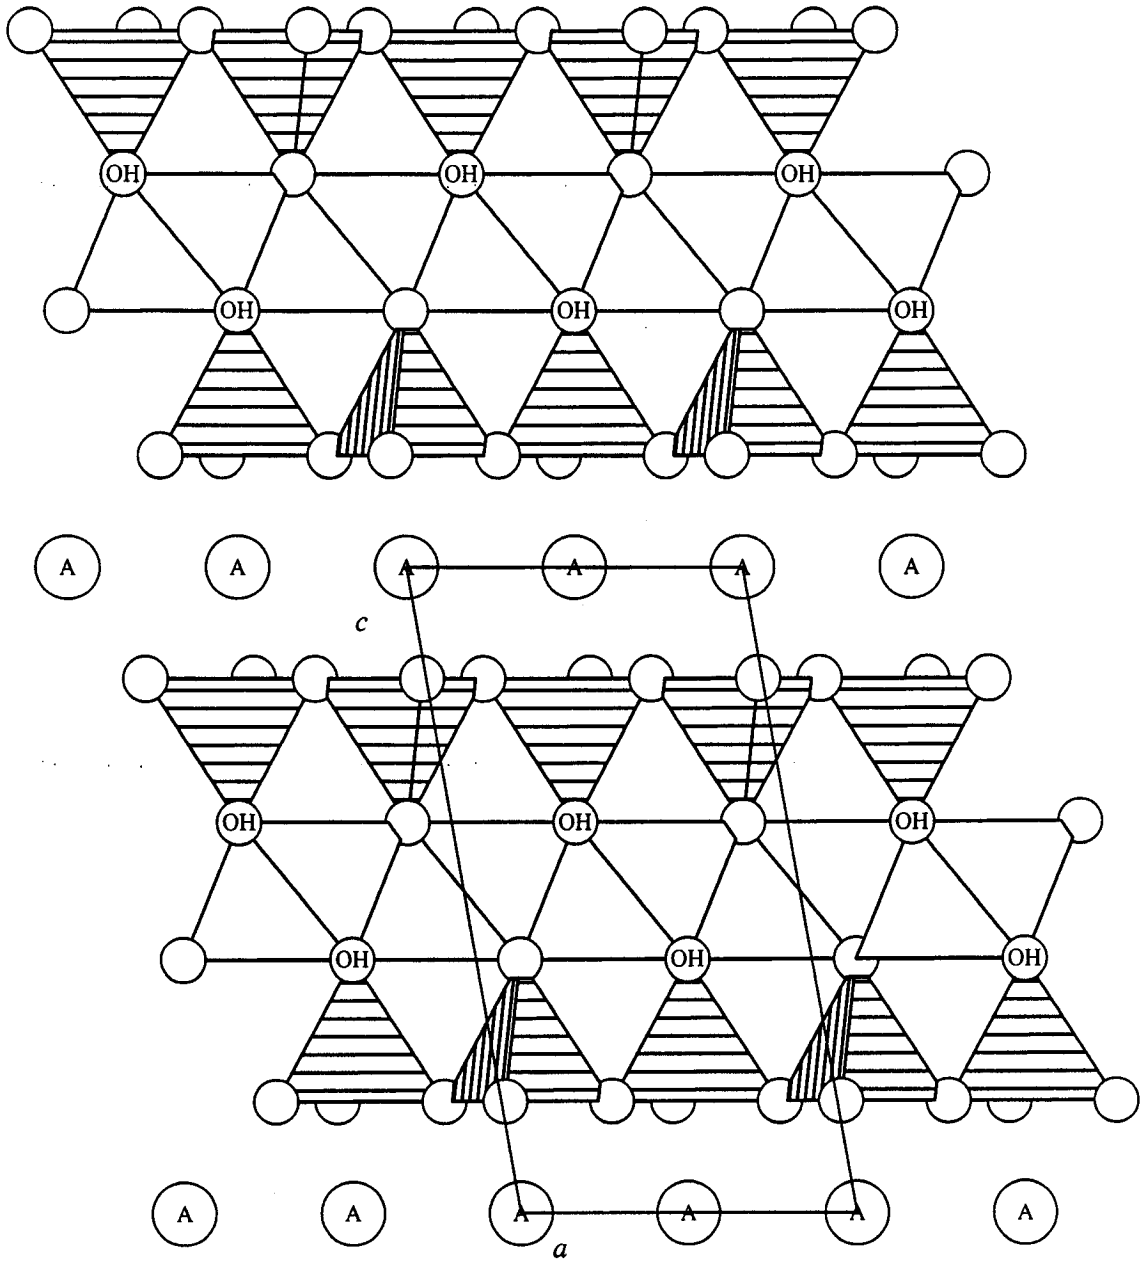

Figure 6.13. (0-10) projection showing the position of the *a* and *c* axes for the conventional 1*M* mica unit layer.

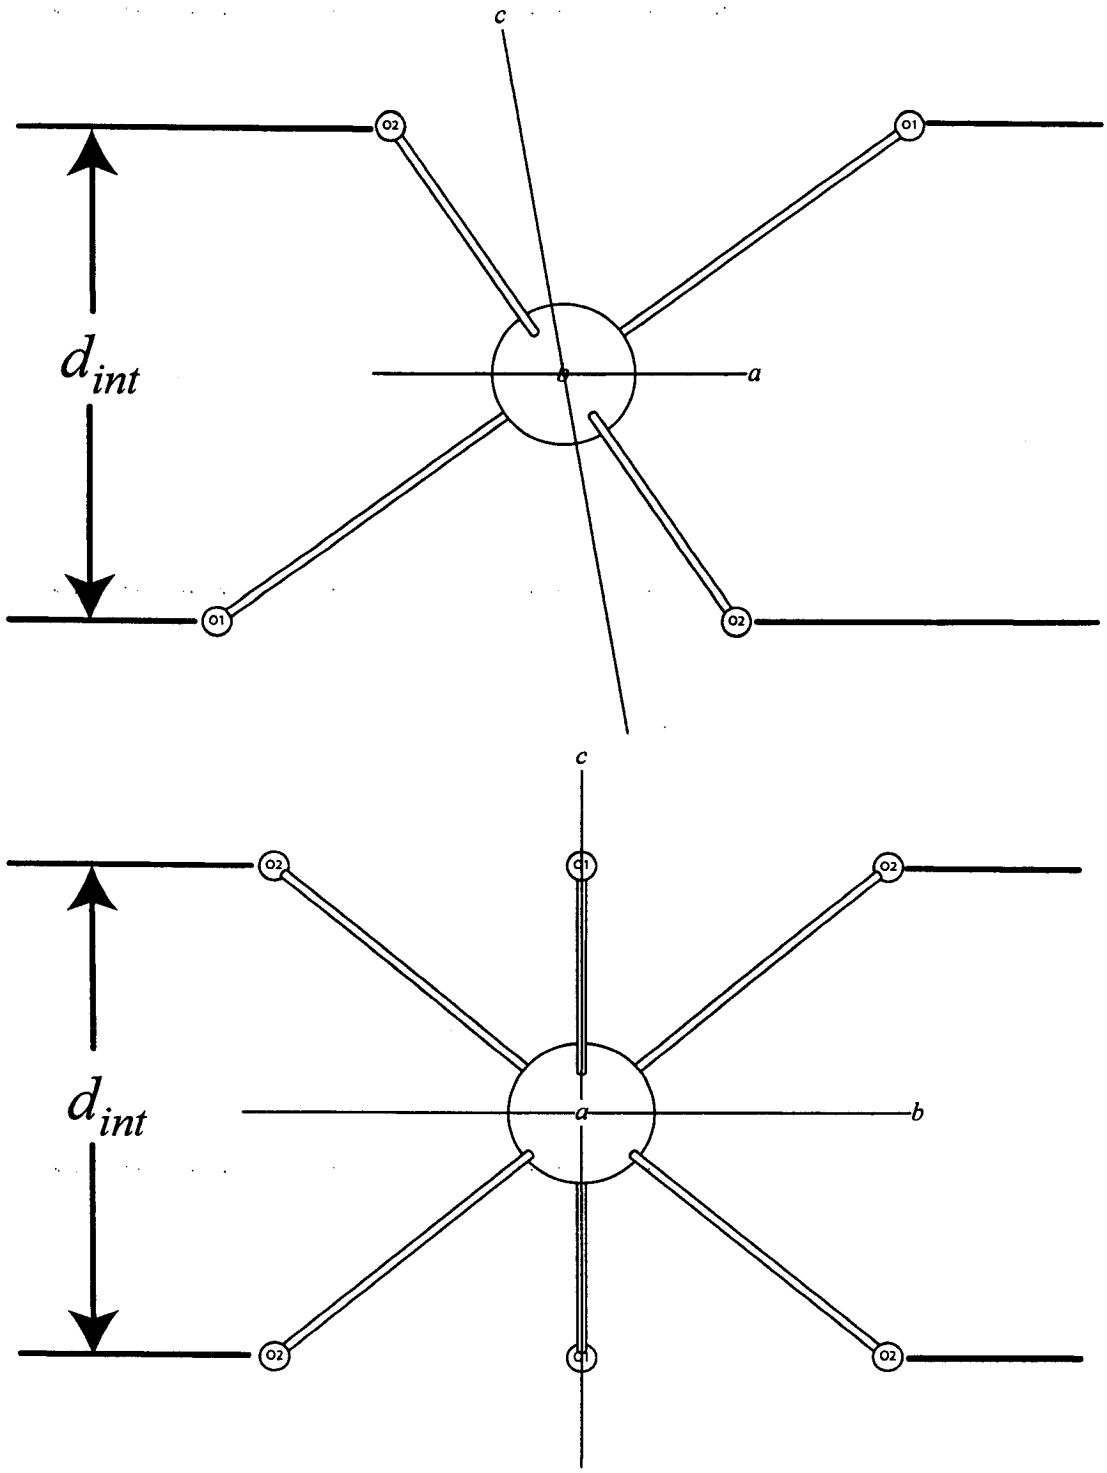

Figure 6.14. Geometry of the inner octahedron located in the interlayer site. See text for an explanation of the various symbols that are shown.

Model Type	Specified Parameters	Parameters that follow
geometric homo-octahedral sheet attached to tetrahedral sheets composed of:	d_o, h_o	a, b, ψ
i) ideal tetrahedrons	d_t, α	a,b,h_t
ii) iso-bond tetrahedrons	d_t, τ_{bas}	h^t_{bas} ,a,b,h_t
iii) aniso-bond tetrahedrons	d_t^{bas}, τ_{bas}	h^t_{bas} ,a,b, τ_{api}
	d_t^{api}	h_t
interlayer site	$(A\text{-}O)_{in}$	d_{int} , c , β
geometric meso-octahedral sheet	h_o, δ_{M2}, d_{M1} (or d_{M2})	d_{M2} (or d_{M1}), ψ_{M1}, ψ_{M2}, a, b
A tetrahedral sheet composed of ideal, iso-bond, or aniso-bond tetrahedrons cannot fit on top of a geometric meso-octahedral sheet (see Subsection 6.3.3 below)		
geometric hetero-octahedral sheet: not considered in this thesis		

Table 6.1. Summary of the different geometrical models presented in Section 6.2.

6.3 Comparison of geometrical models with single-crystal 1*M* structures

The vast majority of 1*M* mica structures have been refined in the space-group type *C*2/*m* (see [Brigatti & Guggenheim 2002]). Excluding hydrogen atoms, this symmetry provides eight independent crystallographic sites (Table 6.2): one interlayer cation site, *A*; two octahedral cation sites, *M*1 and *M*2; one tetrahedral site cation site, *T*; two basal oxygen anion sites, *O*1 and *O*2; one apical oxygen anion site, *O*3; and one OH/F anion site, *O*4. We have compiled 170 crystal structure refinements of 1*M* structures, tabulated in Appendix P, for the purpose of comparisons with our geometrical models that are reported in this thesis.

Table 6.3 lists the crystallographically independent cation-anion bond lengths, anion-anion distances (edge lengths), and selected bond angles for the octahedral, tetrahedral, and interlayer sites, along with their multiplicities. The quantities specified in Table 6.3 were calculated for all 1*M* structures tabulated in Appendix P and are compiled therein.

Atom	Multiplicity	Wyckoff	Site Symmetry
A	2	b	2/*m*
M1	2	c	2/*m*
M2	4	h	2
T	8	j	1
O1	4	i	m
O2	8	j	1
O3	8	j	1
O4	4	i	*m*

6.3.1 Distortions of octahedrons

Figures 6.15 and 6.16 show the variations of individual cation-anion distances as a function of average octahedral bond lengths for the *M*1 and *M*2 sites, respectively, for a suite of crystal structure refinements of 1*M* structures tabulated in Appendix P .

In the *M*1 octahedrons, (M1-O3) and (M1-O4) distances increase linearly with the average <M1-O> at slightly different rates. In contrast with [Toraya 1981], who concluded an almost constant difference of 0.05 Å between (M1-O3) and (M1-O4), it is observed that the differences between these two distances increase as <M1-O> decreases. Note that the study of [Toraya 1981] was based on a survey including only fifteen (15) 1*M* mica structures, whereas Figure 6.15 includes 170 structures.

In the case of *M*2 octahedrons (Figure 6.16), the systematics displayed by the variations of the (M2-O3), (M2-O3'), and (M2-O4) distances with the average <M2-O> are somewhat poorer. In general (M2-O3) and (M2-O3') are larger than (M2-O4) for a given structure, except for Rietveld-refined synthetic annite-syderophyllite structures which display the opposite behaviour — i.e., (M2-O4) > (M2-O3), (M2-O3') (see Figure 6.16, bottom). The three M2-O distances increase more or less linearly with <M2-O> at approximately the same rate, except for a few samples that are numbered individually on a separate blow-up (Figure 6.16, bottom).

Extrema and notable exceptions in Figures 6.15 and 6.16 are (see Table 1.1 for nomenclature): lepidolite, Nos. 28, 65, 144; paragonite, No. 147; clintonite, Nos. 46-48, 68, 129-134; preiswerkite, Nos. 51-52; norrishite, No. 80; synthetic tetra-Ge-phlogopite, Nos. 71, 79; synthetic Cs-tetra-ferri-annite, Nos. 44-45; a Mn-rich biotite sample, No. 32; an annite sample, No. 165; oxybiotite, Nos. 27, 53; a synthetic Mn-F-Mg-mica sample, No. 74; a hydrogenated-biotite sample, No. 67; Rietveld-refined synthetic annite-syderophyllite samples, Nos. 55-62; and some biotite specimens, Nos. 1, 96, 100-102 ($[Ti]_{apfu} \approx 0.6$), 114-115 & 118 ($[Ti]_{apfu} \approx 0.4$, Ba-rich), 145, 150.

The observation that M-O4 distances are smaller than M-O3 distances for the *M*1 and *M*2 sites can be (partially) understood in terms of an electrostatic repulsion between the interlayer cations and the OH-group protons. The interlayer cations exert electrostatic forces on the protons that cause a displacement (depression) of the OH groups towards the plane of octahedral cations, that is also most likely accompanied with a certain bending of the O-H dipole direction. The overall effect is that the apical oxygen atoms located in the *O*3 site are *not* coplanar with the OH-groups of the *O*4 site, i.e. $O3_z \neq O4_z$.

Such effects (unequal M-O bond lengths and non-co-planar O3 and O4 atoms) were not

taken into account in the geometrical models presented in Section 6.2 and shall now be addressed. Consider the distorted *M*1 and *M*2 octahedrons that are shown in Figure 6.17. If the depression of the O4 sites occurs on axes perpendicular to the plane of octahedral cations, then, in terms of the (M1-O3) bond length and the observed depression $(O4z - O3z)\cdot c\cdot \sin\beta$, one can predict the (M1-O4) bond length to be given by:

$$(M1-O4) = \sqrt{\begin{array}{l}(M1-O3)^2 \sin^2\psi_{M1-O3} + \\ \left[(M1-O3)\cos\psi_{M1-O3} - (O4z-O3z)c\sin\beta\right]^2\end{array}} \tag{6.26}$$

where ψ_{M1-O3} represents the flattening angle of the individual (M1-O3) bond length with respect to the *c**-direction. Using the *O*3 positions reported in Appendix P, ψ_{M1-O3} can be written as

$$\psi_{M1-O3} = \arccos\left[\frac{(\tfrac{1}{2} - O3z)c\sin\beta}{(\mathrm{M1-O3})}\right] \tag{6.27}$$

Similarly, one can also predict the (M2-O4) bond lengths. In this case, since the (M2-O3) and (M2-O3') distances are not necessarily equal, three separate predictions can be obtained:

$$(M2-O4) = \sqrt{\begin{array}{l}(M2-O3)^2 \sin^2\psi_{M2-O3} + \\ \left[(M2-O3)\cos\psi_{M2-O3} - (O4z-O3z)c\sin\beta\right]^2\end{array}}$$

$$(M2-O4) = \sqrt{\begin{array}{l}(M2-O3')^2 \sin^2\psi_{M2-O3'} + \\ \left[(M2-O3')\cos\psi_{M2-O3'} - (O4z-O3z)c\sin\beta\right]^2\end{array}}$$

$$(M2-O4) = \sqrt{\begin{array}{l}\left[\frac{(M2-O3)+(M2-O3')}{2}\right]^2 \sin^2\psi_{M2-O3} + \\ \left[\left(\frac{(M2-O3)+(M2-O3')}{2}\right)\cos\left(\frac{\psi_{M2-O3}+\psi_{M2-O3'}}{2}\right) - (O4z-O3z)c\sin\beta\right]^2\end{array}} \tag{6.28}$$

where

$$\Psi_{M2\text{-}O3} = \arccos\left[\frac{(\tfrac{1}{2} - O3z)c\,\sin\beta}{(\mathrm{M2 - O3})}\right]$$

(6.28)

$$\Psi_{M2\text{-}O3'} = \arccos\left[\frac{(\tfrac{1}{2} - O3z)c\,\sin\beta}{(\mathrm{M2 - O3'})}\right]$$

Figure 6.18 compares observed (M1-O4) and (M2-O4) bond lengths to predictions made using Eqs. 6.25 and 6.27. Extrema and notable exceptions in Figure 6.18 are the same as those discerned for Figures 6.15 and 6.16, with the addition of two structures: biotite, No. 143 ($[Ti]_{apfu} \approx 0.3$); and ferrokinoshitalite, No. 81.

The degree to which the data points coincide with each of the 1:1 correspondence lines indicates how adequate our O4-site depression model of Figure 6.17 is insofar as predicting individual octahedral bond lengths on a given crystallographic *M*-site. The agreement of the model with the data is within ~0.02 Å and ~0.04 Å for the *M*1 and *M*2 sites, respectively, excluding the above mentioned exceptions.

Cases severely incongruent with the *O*4-site depression model for either the *M*1 or *M*2 sites are: norrishite, No. 80; and biotite, No. 145. There is nothing special with the latter biotite specimen except for a relatively high agreement factor *R* of 13.5 % , whereas norrishite was already pointed out in Figure 6.3 as a exception to the hexagonal pseudo-symmetry demonstrated by the $b = \sqrt{3} \cdot a$ relationship (Section 6.1). In addition, Rietveld-refined synthetic annite-syderophyllite structures Nos. 55-62 are systematically shifted from the 1:1 correspondance lines.

It is interesting to notice that clintonite (Nos. 46-48, 68, 129-134), preiswerkite (Nos. 51-52), lepidolite (Nos. 28, 65, 144), and paragonite (No. 147) structures agree with the model in the case of *M*1 sites except for Nos. 68 and 147, but not for *M*2 sites where it is seen (Figure 6.18) that predicted values are smaller than observed (M2-O4) bond lengths in all cases — the ideal octahedral sheet content of each species is $[Mg_2Al]$ for clintonite and preiswerkite, $[Li_{2\text{-}1.5}Al_{1\text{-}1.5}]$ for lepidolite, and $[Li_2\square]$ for paragonite.

On the other hand, there are structures — namely, oxybiotite, Nos. 27, 53; a tetra-Ge-mica, No. 71; a hydrogenated-biotite, No. 67; biotite, Nos. 96, 100-102, 114-115 & 118, 143, 145, 150 — that display an opposite behaviour: predicted values are higher than observed (M2-O4) bond lengths, whereas (M1-O4) predicted and observed distances show a fair agreement. In general, these structures also stand out on Figure 6.16 (bottom).

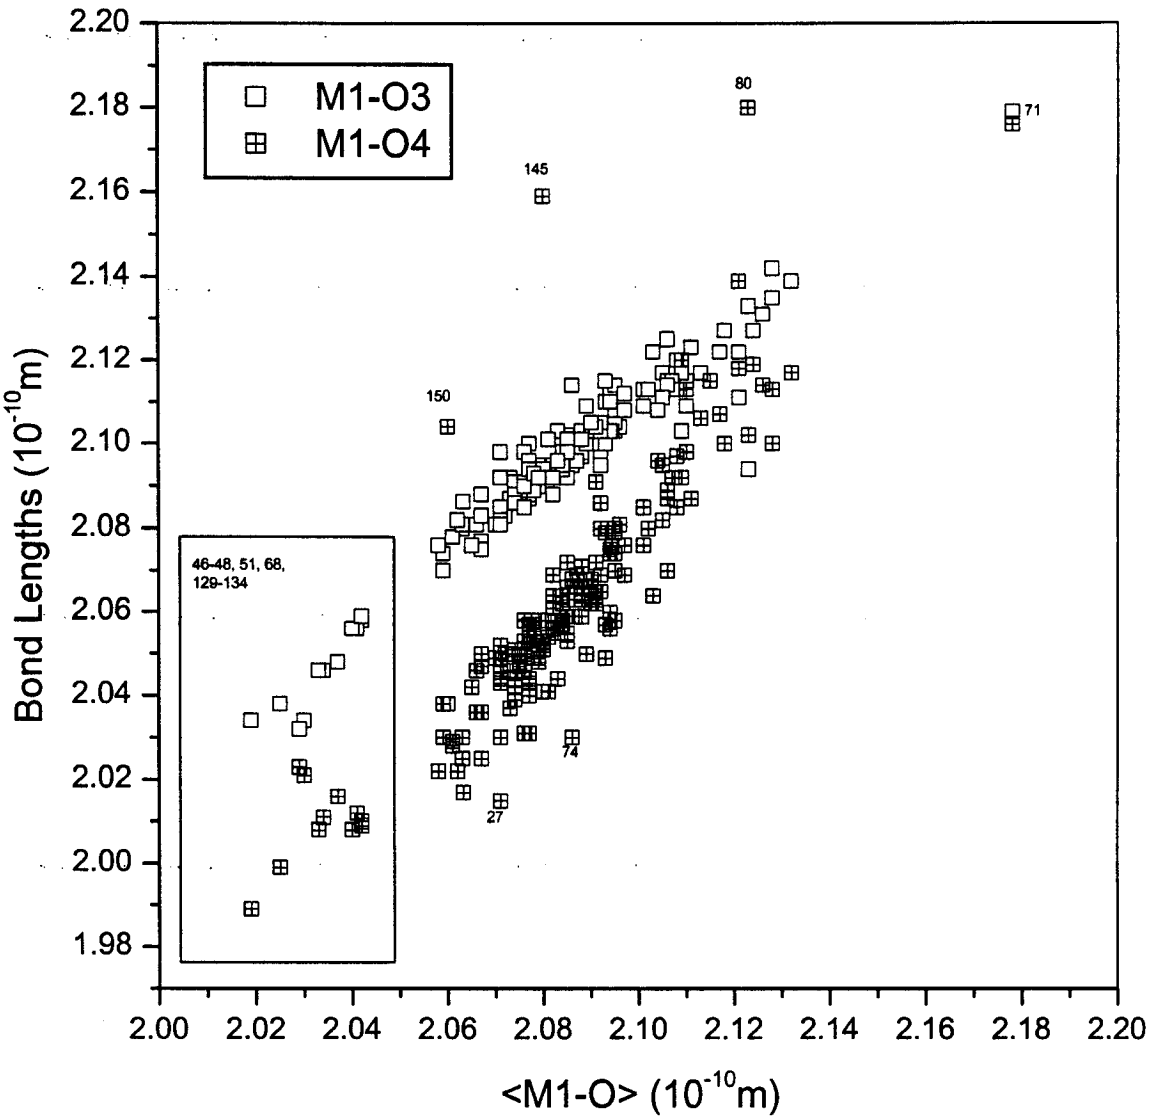

Figure 6.15. Variations of individual bond lengths for the *M*1 sites. Samples labelled with their corresponding structure Nos. (Appendix P) are discussed in the text.

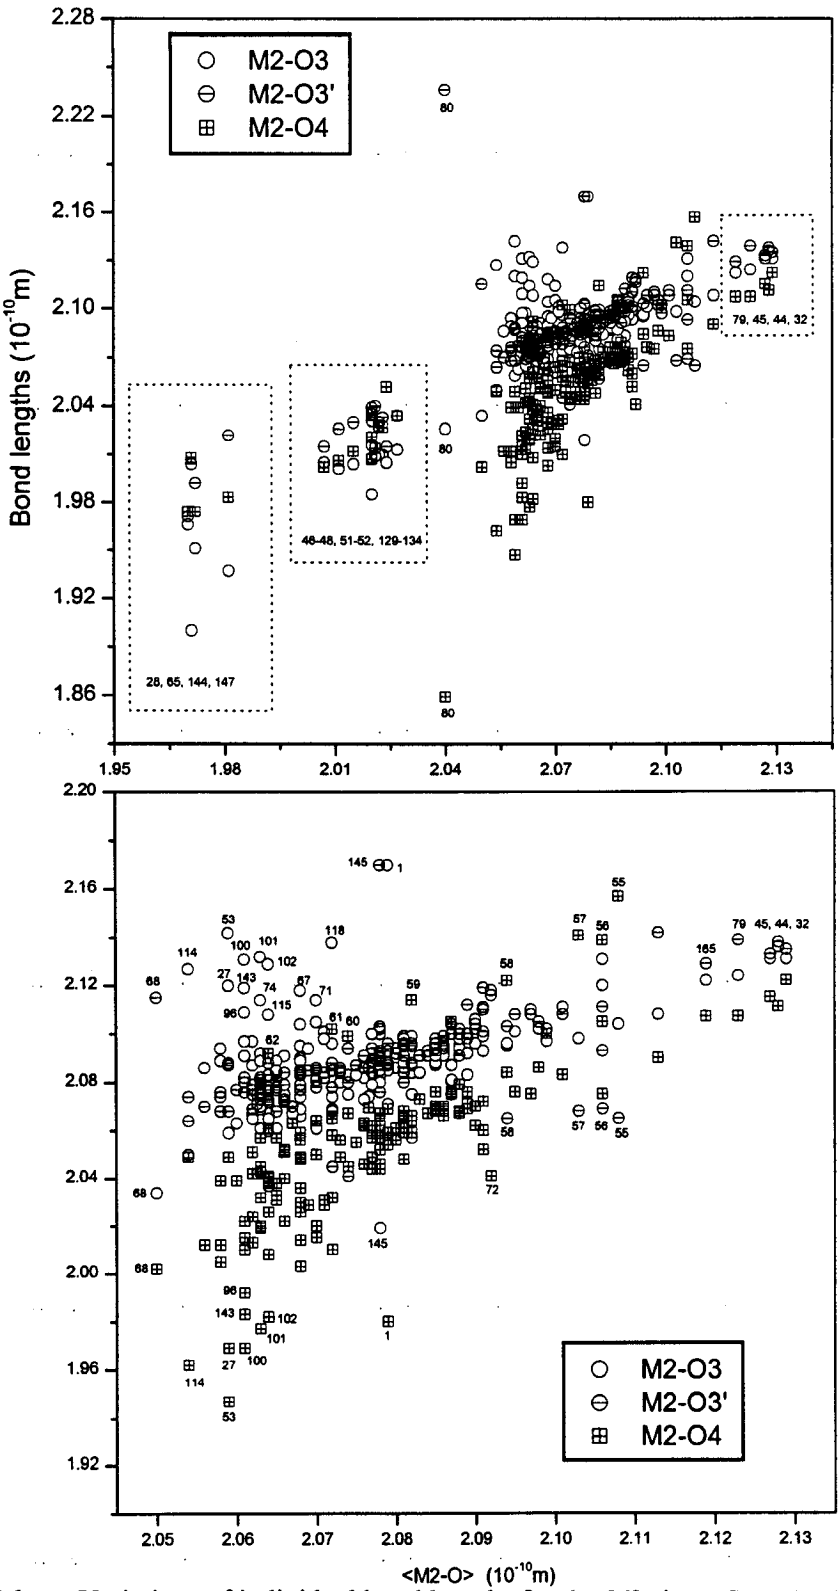

Figure 6.16. Variations of individual bond lengths for the *M*2 sites. Samples labelled with their corresponding structure Nos. (Appendix P) are discussed in the text.

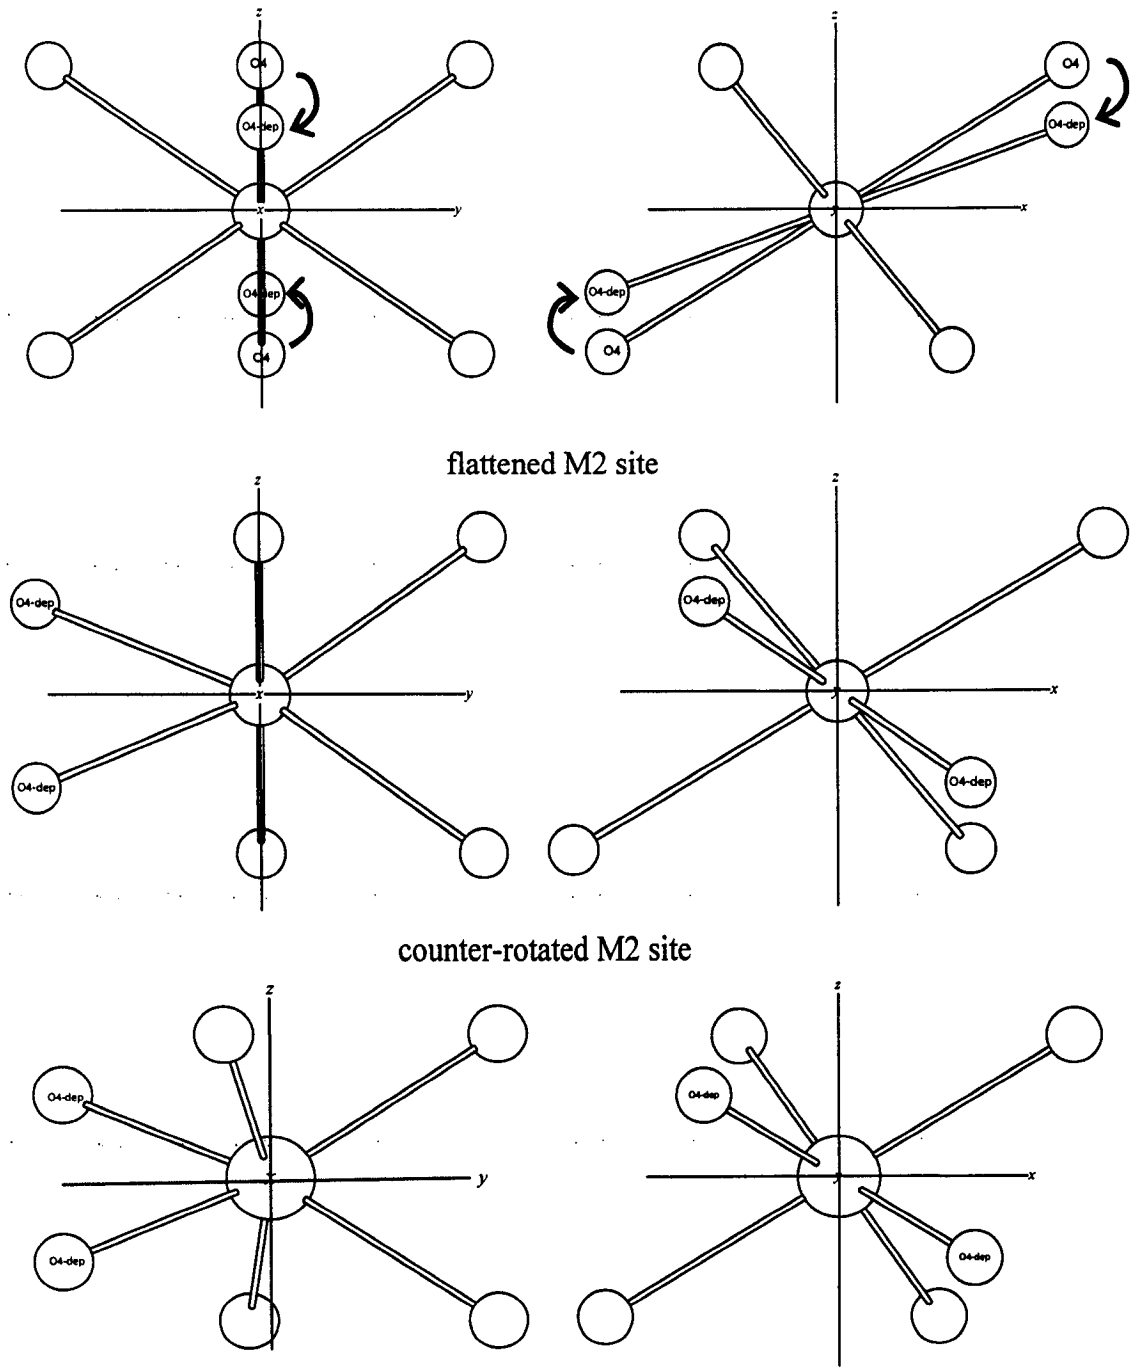

Figure 6.17. Geometrical model for the depression of the *O*4 site. See text for an explanation of the model.

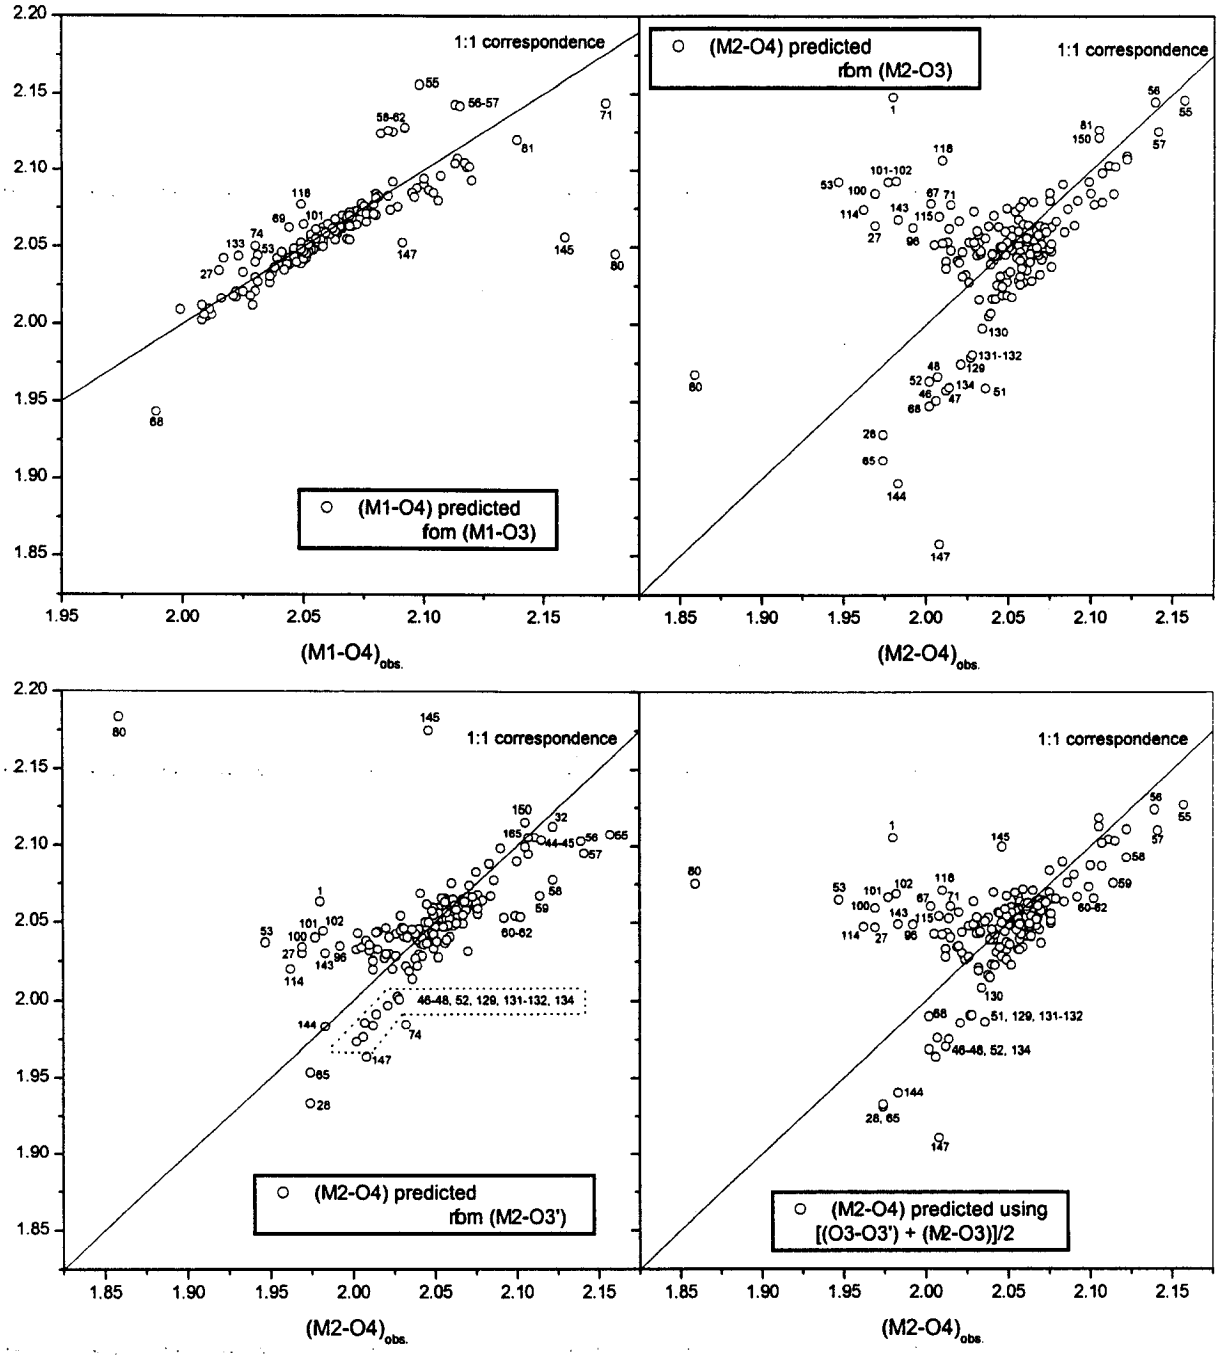

Figure 6.18. Comparison of observed (M1-O4) and (M2-O4) bond lengths with predictions made using the *O*4-depression model presented in Figure 6.17.

Let us now examine the systematics displayed by the octahedral edges. Figures 6.19 and 6.20-6.21 show the variations of individual *shared edge* lengths with their average values $\langle e_s \rangle$ in *M*1 and *M*2 octahedrons, respectively. The solid lines drawn in these figures indicate a 1:1 correspondence between the *x* and *y* axes. Notable exceptions are the same as those pointed out for Figures 6.15, 6.16, and 6.18.

In *M*1 octahedrons (Figure 6.19), (O3-O3) and (O3-O4) increase approximately linearly along the 1:1 correspondence lines, showing more scatter for the (O3-O3) edges. In accordance with our *O*4-site depression model (Figure 6.17), (O3-O3) edge lengths are usually larger than those of (O3-O4). In *M*2 octahedrons (Figure 6.20 and 6.21), the lengths of the shared edges are generally in the order (O3-O3) > (O3-O4) > (O4-O4), and are hence also in agreement with our *O*4 depression model.

Among the four individual shared edge lengths of *M*2 octahedrons (Figure 6.21), two of them refer to edges shared between *M*1 and *M*2 octahedrons, $(O3\text{-}O3)^{M1\text{-}M2}$ and $(O3\text{-}O4)^{M1\text{-}M2}$, and the remaining two correspond to edges shared between two *M*2 octahedrons, $(O3\text{-}O3)^{M2\text{-}M2}$ and $(O4\text{-}O4)^{M2\text{-}M2}$. As previously explained in Subsection 6.2.1, the shared edge lengths also depend on the angle of counter-rotation of a given octahedron.

Counter-rotation angles of *M*2 octahedrons, δ_{M2}, were calculated in a manner similar to [Weiss *et al.* 1985] (i.e. $\delta_{M2} = \delta_{Weiss}/2$, see Figure 6.27 below) and are tabulated in Appendix P. In *M*1octahedrons, when obtained as in [Weiss *et al.* 1985], counter-rotation angles are zero by symmetry.

The relationships between shared edge lengths and counter-rotation angles are illustrated Figure 6.22, where differences $[(O3\text{-}O3)^{M1\text{-}M2} - (O3\text{-}O3)^{M2\text{-}M2}]$ and $[(O3\text{-}O4)^{M1\text{-}M2} - (O4\text{-}O4)^{M2\text{-}M2}]$ are plotted as a function of δ_{M2}. In an ideally flattened and counter-rotated octahedron, as mentioned in Subsection 6.2.1, $O3z = O4z$ and the six shared edges of a given octahedron fall into two groups of three, where the edge lengths for each group are given by Eq. 6.8. In 1*M* structures, however, $O3z \neq O4z$ and one additional degree of freedom is hence possible.

Nevertheless, as emphasized by the short-dash lines drawn on Figure 6.22 as guides to the eye, the plotted differences evolve linearly with δ_{M2}, the scatter being much narrower in cases involving *O*3 atoms only. This means that shared edge lengths depend first on the degree of counter-rotation, and then on the amount of depression of the *O*4 site.

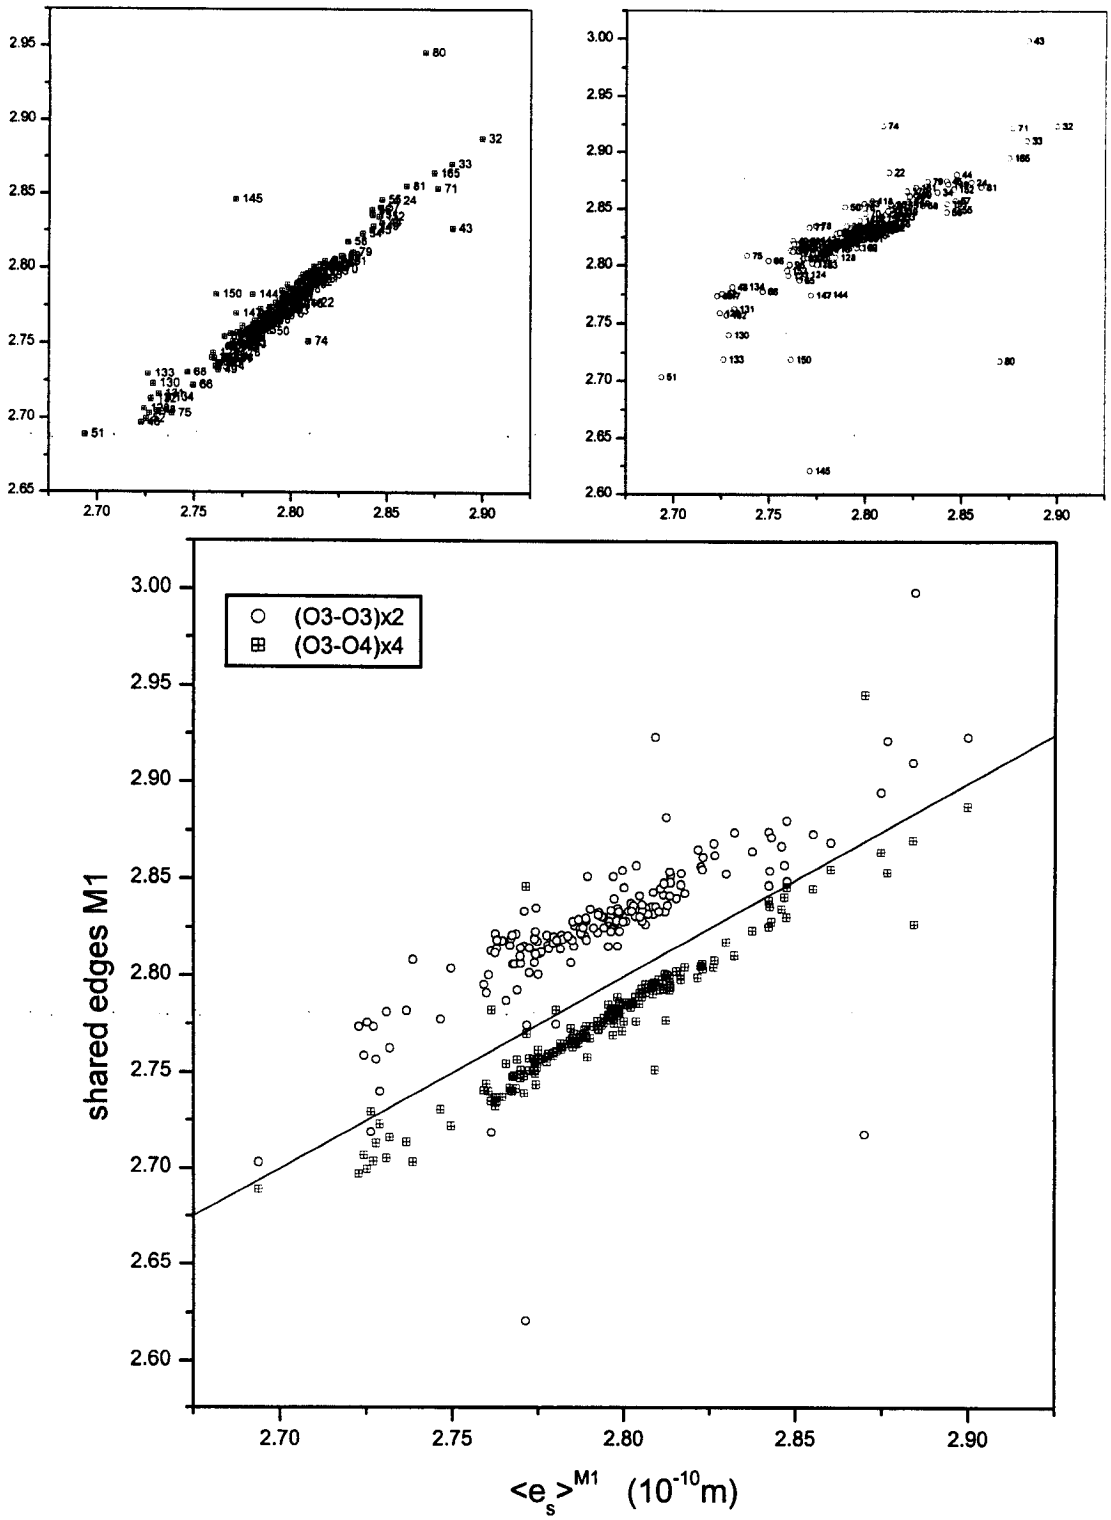

Figure 6.19. Variations of individual shared edges with their averages values for the *M*1 octahedrons. The solid line is a 1:1 correspondence between *x* and *y* axes.

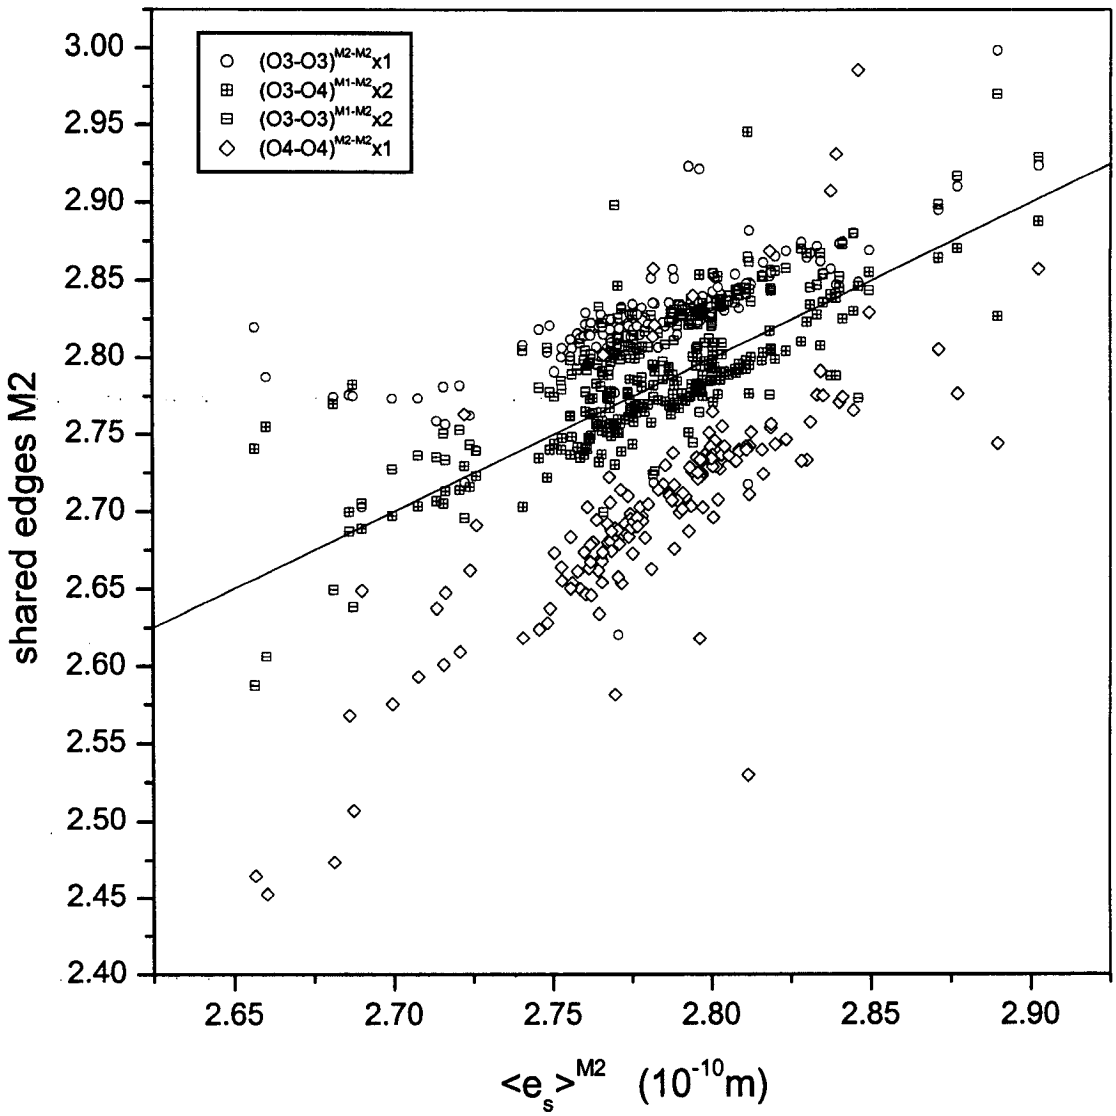

Figure 6.20. Variations of individual shared edges with their average values for the *M*2 octahedrons. The solid line is a 1:1 correspondence between *x* and *y* axes.

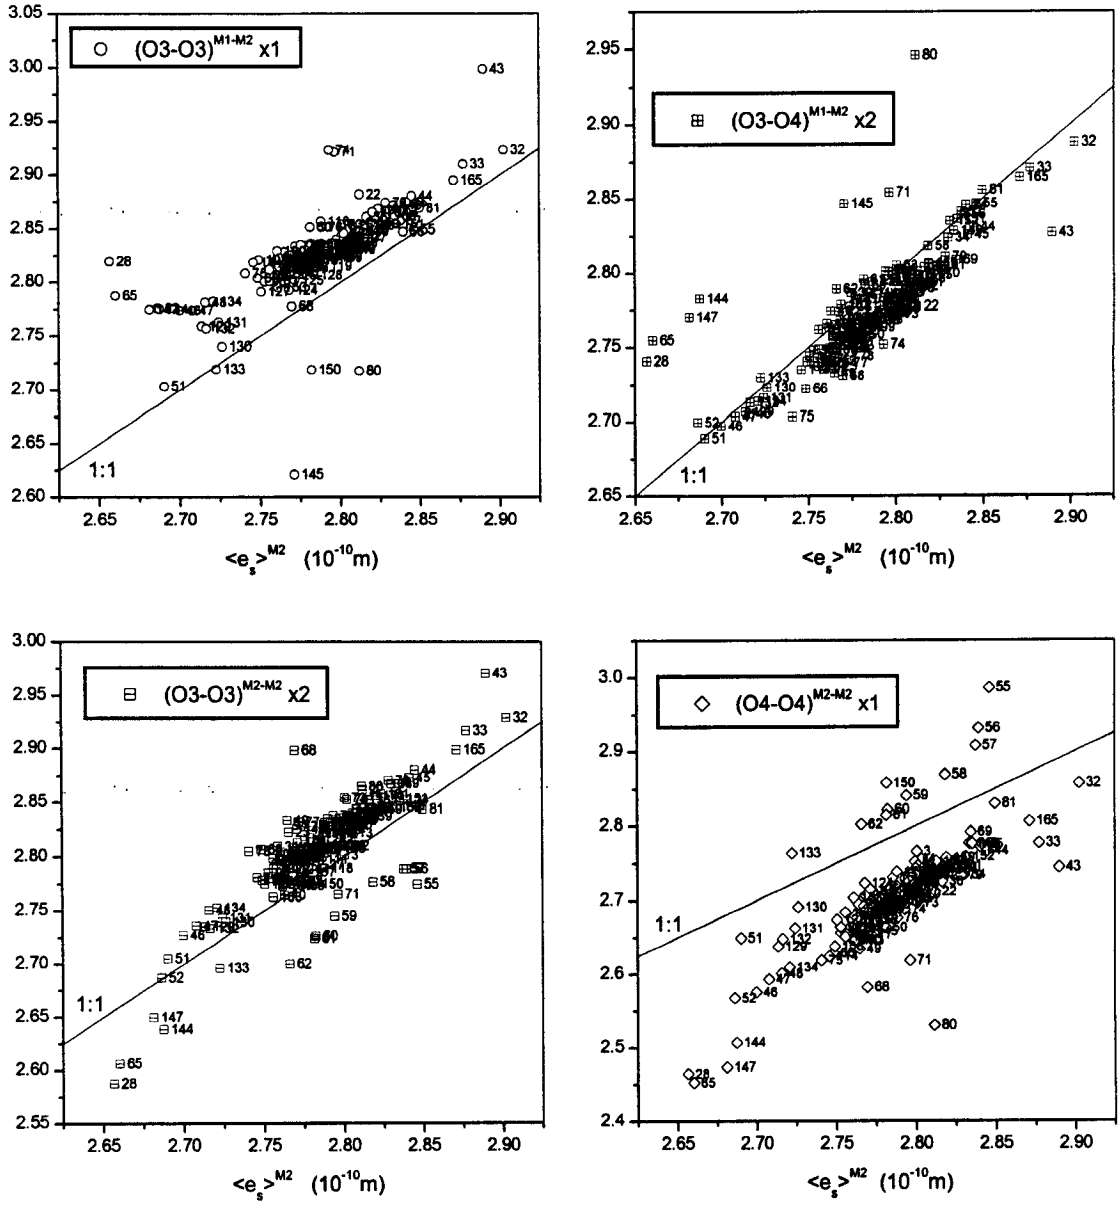

Figure 6.21. Identification of data points plotted in Figure 6.20. The solid lines are 1:1 correspondence between *x* and *y* axes.

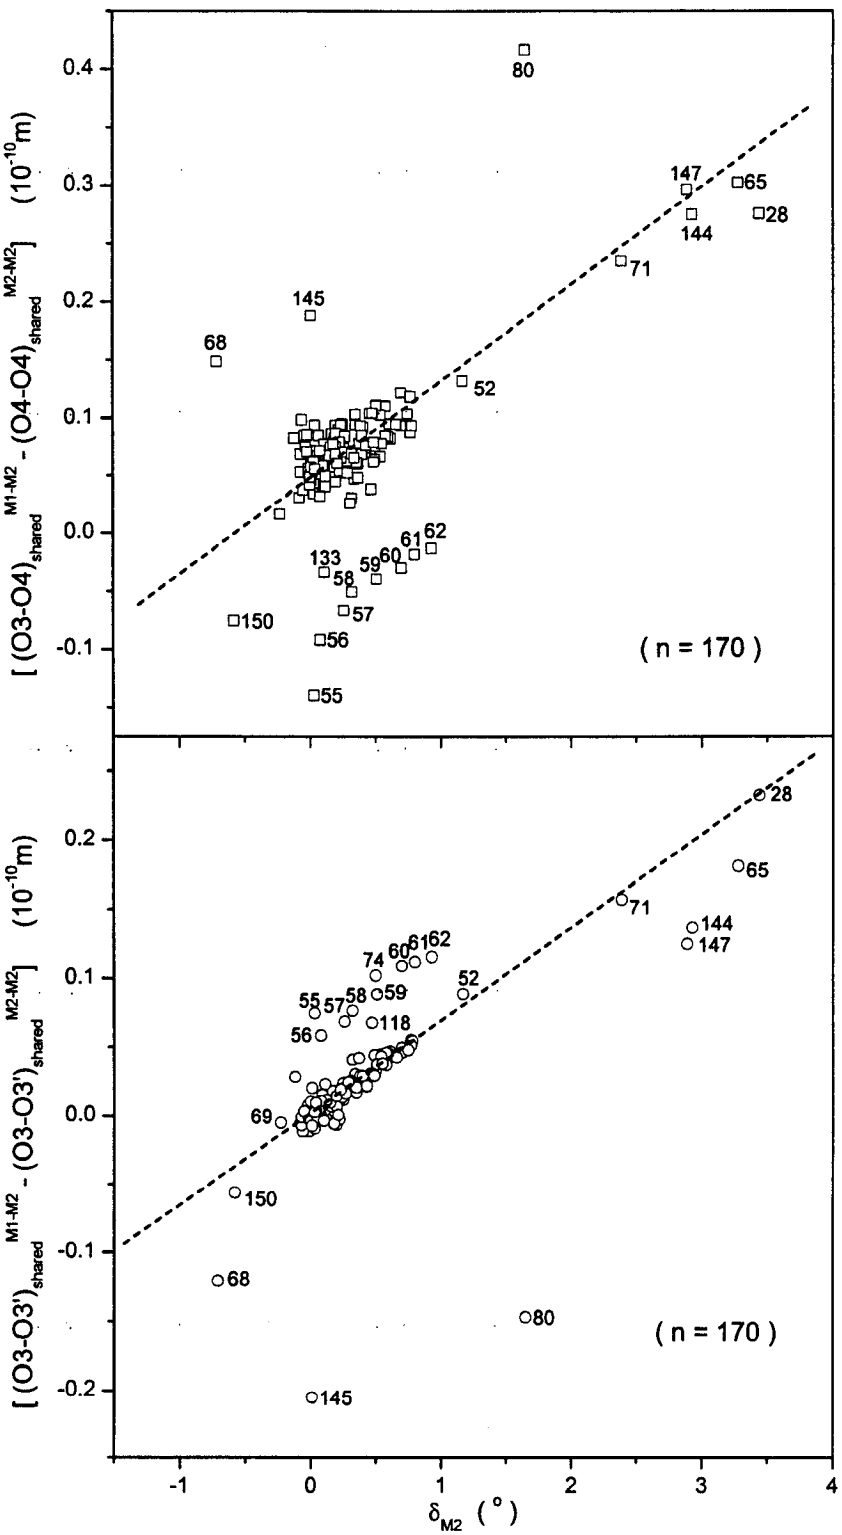

Figure 6.22. Shared edge length differences in *M*2 octahedrons as a function of counter-rotation angles δ_{M2}. The dashed lines are guides to the eye.

Figures 6.23 and 6.24-6.25 present the variations of individual *unshared edge* lengths with their average values $<e_u>$ in *M*1 and *M*2 octahedrons, respectively. Given the space-group symmetry positions occupied by the *M*1, *O*3, and *O*4 atoms, it follows that in *M*1 octahedrons top and bottom triangular faces formed by unshared edges are at least isosceles, with an *M*1 cation lying at the centre of mass of each *M*1 octahedron. When (O3-O4) and (O3-O3) distances are equal, the triangular faces are equilateral; Figure 6.23 gives the extent to which this is the case.

On the other hand, from space-group symmetry positions, an *M*2 cation is not necessarily at the centre of mass of an *M*2 octahedron, while top and bottom triangular faces formed by the unshared edges are in principle scalene. However, Figure 6.24 (bottom) demonstrates that *M*2 triangular faces are actually at least isosceles, (O3'-O4) being essentially always equal to (O3-O3'). The only exception to this observation is the norrishite structure, No. 80.

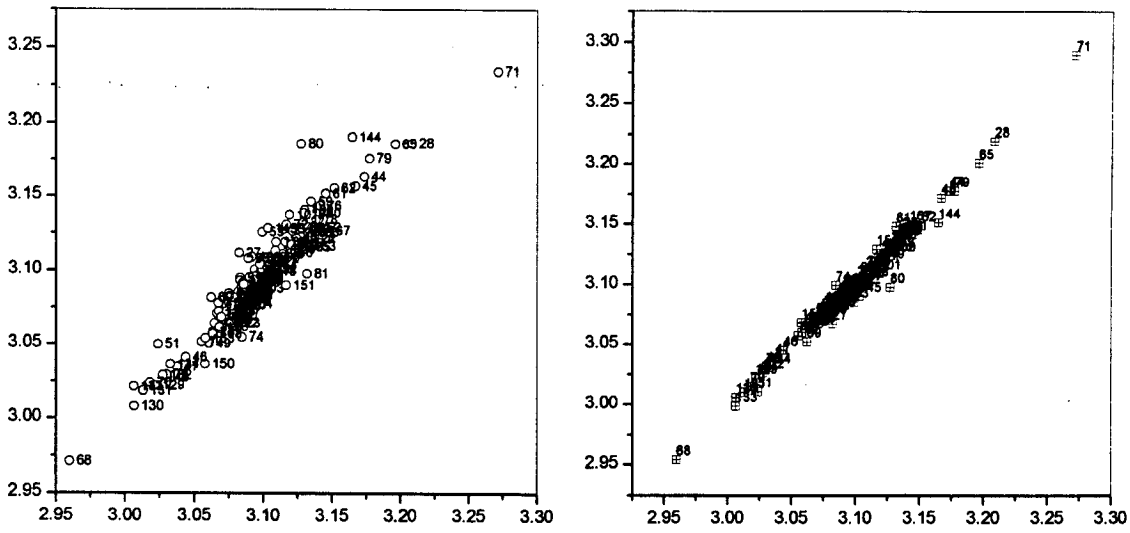
The ratio between the two uneven side lengths of an isosceles triangle can be taken as a measure of its 'degree of isosceles-ness'. In Figure 6.26, ratios (O3-O4)/(O3-O3') for *M*1octahedrons are plotted as a function of ratios {[(O3-O3')+(O3'-O4)]/2}/(O3-O4)} for *M*2 octahedrons. Given that the data points approximately follow the 1:1 correspondence line between the *x* and *y* axes, one concludes that the degree of isosceles-ness of *M*1 and *M*2 octahedrons are related one to another.

The latter observation can be linked to the in-plane distortion angle ε_{M1}, which is defined as the angle between the direction of the *a* axis and the projection of an (M1-O3) bond length on the *a-b* plane (see Figure 6.27). For an ideal or flattened octahedron located at the *M*1 site, $\varepsilon_{M1} = 60^{\circ}$; this condition applies for geometric homo-octahedral and geometric meso-octahedral sheets (Figures 6.5 and 6.6, respectively), but it is not imposed by the space-group symmetry of the *O*3 site in a 1*M* structure. Values of ε_{M1} were calculated for *M*1 octahedrons and are tabulated in Appendix P.

Figure 6.28 shows ratios (O3-O4)/(O3-O3') and {[(O3-O3')+(O3'-O4)]/2]}/(O3-O4) for *M*1and *M*2 octahedrons, respectively, as a function of ε_{M1}. Besides the usual exceptions noted so far, one can observe linear correlations between unshared edge length ratios and ε_{M1} for both *M*1 and *M*2 octahedrons, which are brought into relief by the short-dash lines drawn as guides to the eye. Therefore, the degree of isosceles-ness of top and bottom unshared triangular faces of *M*1 and *M*2 octahedrons is caused by the in-plane distortion angle ε_{M1} of the *M*1 site.

Even though unshared edge lengths are not affected by counter-rotation in an ideally flattened and counter-rotated octahedron (see Subsection 6.2.1), one could nonetheless expect a relation to hold between ε_{M1} and δ_{M2} since the isosceles-ness of *M*1 and *M*2 unshared faces are linked together through ε_{M1}. However, as shown in Figure 6.29, where values of ε_{M1} are

plotted as a function of δ_{M2}, there is no correlation between these two parameters.



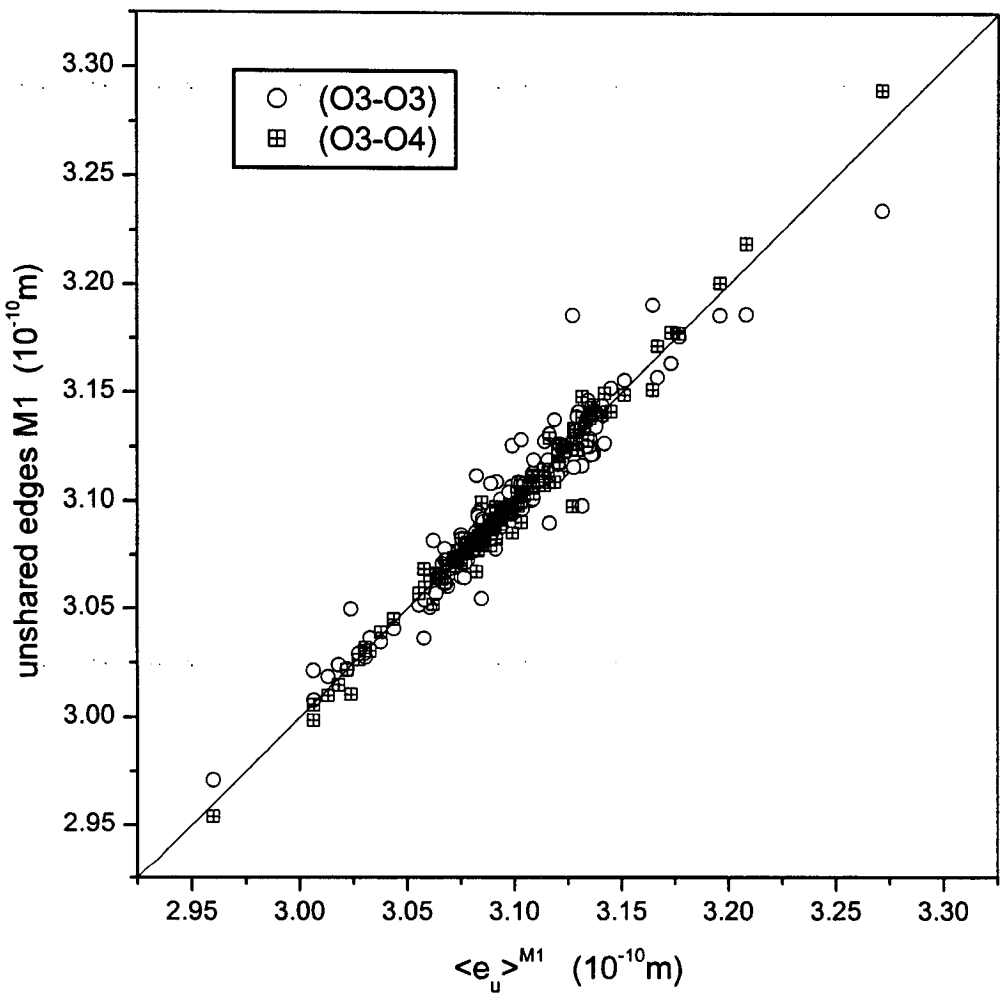


Figure 6.23. Variations of individual unshared edges with their average values for the *M*1 octahedrons. The solid line is a 1:1 correspondence between the *x* and *y* axes.

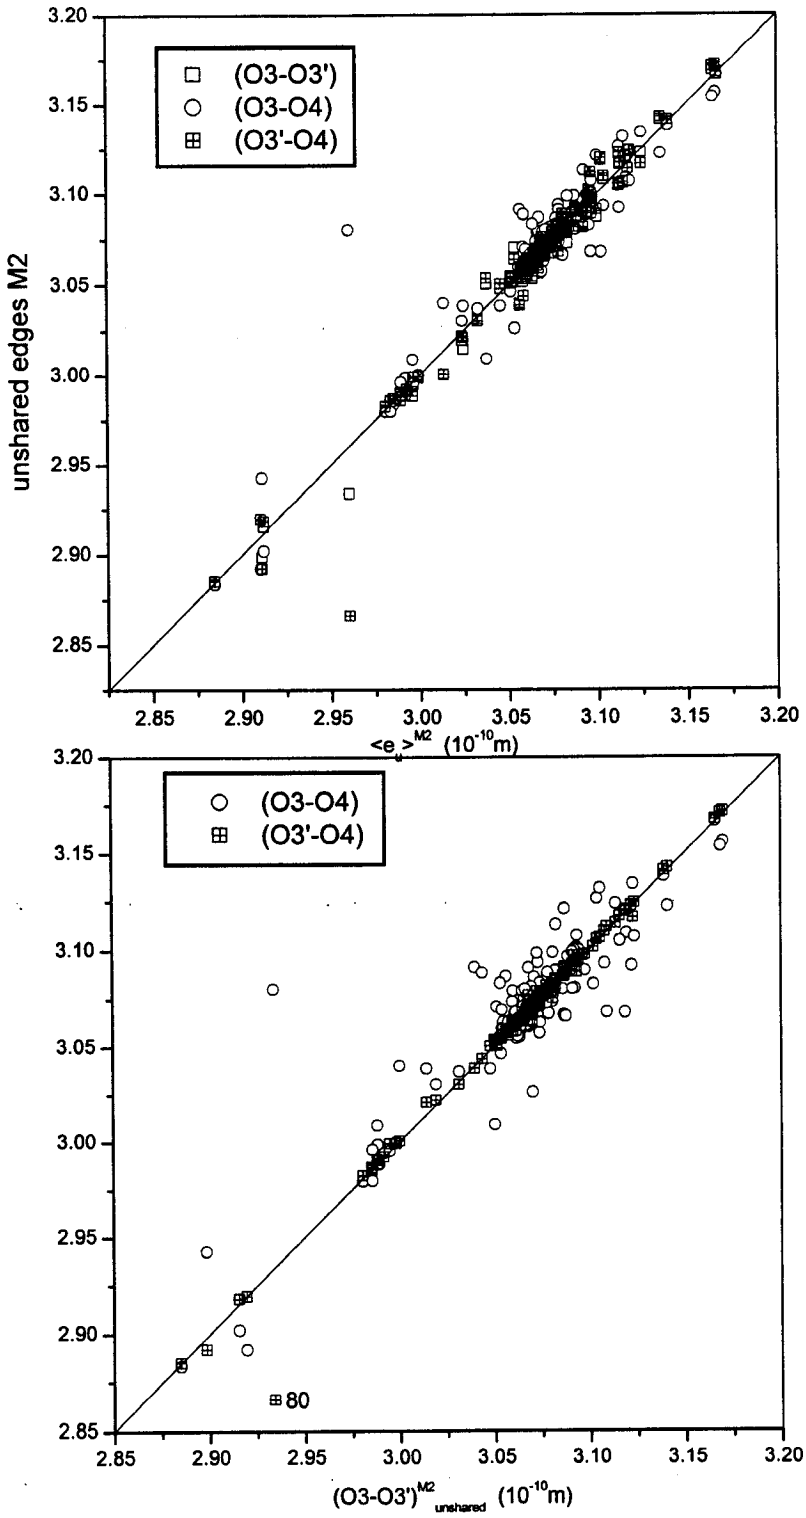

Figure 6.24. Variations of individual unshared edges with their average values for the *M*2 octahedrons. The solid line are 1:1 correspondence between the *x* and *y* axes.

6.3.2 Octahedral sheet distortions

In the preceding subsection, individual bond lengths and edge lengths of *M*1 and *M*2 sites were investigated thoroughly. In the present subsection, we now turn to octahedral sheet distortions.

Figures 6.30 and 6.31 compare lattice parameter predictions made for *a* and *b*, respectively, that were achieved using either: i) a geometric homo-octahedral sheet model via Eq. 6.12 (Figure 6.5) , or ii) a geometric meso-octahedral sheet model via Eq. 6.14 (Figure 6.6).

In the case of geometric homo-octahedral predictions, the average octahedral sheet bond length, <M-O>, and flattening angle, <ψ>, are given by:

(6.30) $$\langle M\text{-}O\rangle = (\langle M1\text{-}O\rangle + 2 \cdot \langle M2\text{-}O\rangle) /3$$

(6.31) $$\langle \psi \rangle = (\psi_{M1} + 2 \cdot \psi_{M2}) /3$$

where ψ_{M1} and ψ_{M2} are obtained from the average octahedral sheet height h_o,

(6.32) $$h_o = 2 \cdot c \cdot \sin\beta \left(\frac{1}{2} - \frac{O4z + 2 \cdot O3z}{3} \right),$$

and the average bond lengths of each of the *M*1 and *M*2 sites, <M1-O> or <M2-O>, as

(6.33) $$\psi_{M1} = \arccos\left[\frac{h_o}{2 \cdot \langle M1 - O \rangle} \right]$$
$$\psi_{M2} = \arccos\left[\frac{h_o}{2 \cdot \langle M2 - O \rangle} \right] .$$

Values of <M-O>, <ψ>, <M1-O>, <M2-O>, h_o, ψ_{M1} and ψ_{M2} are compiled in Appendix P. For geometric meso-octahedral predictions, values of counter-rotation angle δ_{M2} calculated as in Figure 6.27 (and referred to in Subsection 6.3.1) are used.

As can be ascertained from the narrow scatter of data points along the 1:1 correspondence lines drawn on each graph displayed in Figures 6.30 and 6.31, geometric homo-octahedral and geometric meso-octahedral predictions (*y*-axis) give equally good agreements with the observed *a* and *b* lattice parameters (labelled as a_{obs} and b_{obs} in Figures 6.30 and 6.31) to within ~0.005 Å.

Equivalent expressions involving unshared edges of top and bottom triangular faces of *M*1 and *M*2 octahedrons, that are also obtained using Eqs. 6.12 and 6.14, give similar agreements (not shown).

Norrishite structure No. 80 constitutes the only outlier discernable in Figures 6.30 and 6.31. It is interesting to note that predicted values of *b* are larger for this sample than observed values, whereas the opposite takes place for *a*. Indeed, this is due to a break of the $b = \sqrt{3}a$ relationship in this sample (Subsection 6.1).

Therefore, to the extent that peculiar site distortions such as those acting in norrishite are absent (which are presumably due to Jahn-teller effects, see [Tyrna & Guggenheim 1991] and [Brigatti & Guggenheim 2002]), in-plane *a* and *b* lattice parameters are adequately predicted using simple geometrical models involving a geometric homo-octahedral sheet or a geometric meso-octahedral sheet, regardless of the individual bond lengths and edge lengths actually occurring on the *M*1 and *M*2 sites.

Consider now the geometry of a geometric meso-octahedral sheet more closely as in Figure 6.61 (Subsection 6.2.3). As previously mentioned, the projection of the *O*3 atom on the *a*-*b* plane must lie on a line making a 60° angle with the direction of the *a* axis. Clearly then, the situation when $\delta_{M2} = 0$ corresponds to a geometric homo-octahedral sheet.

The sides of the triangle delimited by the projections of the *M*1, *M*2, and *O*3 atoms on the *a*-*b* plane are of lengths: $d_{M1}\sin\psi_{M1}$ for M1-$O3_{xy}$, $d_{M2}\sin\psi_{M2}$ for M1-$O3_{xy}$, and $a/\sqrt{3}$ for *M*1-*M*2. Hereafter, the subscript 'xy' is used to designate a projection on the *a*-*b* plane. Using a few trigonometric identities and a sine law applied specifically to this triangle, one can show that the following relation holds

$$\frac{a/\sqrt{3}}{\sin(120^\circ - \delta_{M2})} = \frac{d_{M1}\sin\psi_{M1}}{\sin 30^\circ} = \frac{d_{M2}\sin\psi_{M2}}{\sin(30 + \delta_{M2})}, \tag{6.34}$$

from which it can be derived that:

$$\frac{d_{M1}\sin\psi_{M1} - d_{M2}\sin\psi_{M2}}{a} = \frac{1}{\sqrt{3}}\left[\frac{\sin(30^\circ + \delta_{M2}) - \sin 30^\circ}{\sin(120^\circ - \delta_{M2})}\right]. \tag{6.35}$$

Equation 6.35 will serve as a basis to explore in-plane intra-layer displacements in Subsection 6.3.5 below.

Next, isolating $d_{M1}\sin\psi_{M1}$ and $d_{M2}\sin\psi_{M2}$ separately in terms of a and δ_{M2} in Eq. 6.35, combined with Eq. 6.9 using Pythagoras' theorem, the following relations arise:

$$d_{M1}{}^2 = \frac{h_o{}^2}{4} + \left(\frac{a}{\sqrt{3}} \cdot \frac{\sin\left[30^\circ + \delta_{M2}\right]}{\sin\left[120^\circ - \delta_{M2}\right]} \right)^2 \tag{6.36a}$$

$$d_{M2}{}^2 = \frac{h_o{}^2}{4} + \left(\frac{a}{\sqrt{3}} \cdot \frac{\sin 30^\circ}{\sin\left[120^\circ - \delta_{M2}\right]} \right)^2 . \tag{6.36b}$$

By subtracting Eq. 6.36b from Eq. 6.36a and factoring out a, one then finds the dimensionless relationship:

$$\frac{d_{M1}{}^2 - d_{M2}{}^2}{a^2} = \frac{1}{3} \frac{\sin^2\left[30^\circ + \delta_{M2}\right] - \sin^2 30^\circ}{\sin^2\left[120^\circ - \delta_{M2}\right]} . \tag{6.37}$$

Eq. 6.37 brings about an interesting geometrical property of an ideal geometric meso-octahedral sheet: The size difference of $M1$ and $M2$ octahedrons is uniquely determined by the degree of counter-rotation of the $M2$ octahedron. The latter relation has not previously been given.

Figure 6.32 shows the normalized size difference $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$ plotted as function of counter-rotation angle δ_{M2} expressed in radians. The solid line drawn in this graph represents a first-order Taylor expansion of the right-hand side of Eq. 6.37 around $\delta_{M2} = 0$, which yields

$$\left[d_{M1}{}^2 - d_{M2}{}^2 \right] / a^2 = 2/9 \cdot \sqrt{3} \cdot \delta_{M2} + \ \ldots Order\left(\delta_{M2}{}^2 \right) . \tag{6.38}$$

The agreement of data points in Figure 6.32 with Eq. 6.38 is remarkable around $\delta_{M2} \approx 0$ and gets worst as δ_{M2} increases, as expected with a Taylor expansion. Norrishite structure No. 80 is again the only exception, but it agrees proportionally better with the predictions than in the case of a and b (Figures 6.30 and 6.31).

Therefore, in accordance with a geometric meso-octahedral sheet model, the normalized size difference $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$ observed in $1M$ mica structures solely depends on the counter-rotation angle δ_{M2}, despite local distortions actually occurring on $M1$ and $M2$ sites.

6.3.3 Distortions of tetrahedrons and tetrahedral sheets

Figures 6.33, 6.34, and 6.35 show individual distances as functions of average lengths for the following quantities, respectively (see Table 6.3 for symbols and nomenclature): i) (T-O1), (T-O2), (T-O2'), and (T-O3) distances *vs.* the average basal tetrahedral bond length $\langle T\text{-}O\rangle_{bas}$; ii) basal edge lengths (O1-O2), (O1-O2'), and (O2-O2') *vs.* the average length $\langle O\text{-}O\rangle_{bas}$; and iii) apical edge lengths (O3-O1), (O3-O2), and (O3-O2') *vs.* the average length $\langle O\text{-}O\rangle_{api}$.

As is well known (see [Brigatti & Guggenheim 2002]for a recent review), Figures 6.34, 6.35, and 6.36 show that bond and edge lengths fall into separate groups that depend on the chemical composition of the tetrahedral sheets: $\langle Al_{\sim 1}Si_{\sim 3}\rangle$ (not labelled, except if falling outside the main trend); $\langle Al_{\sim 3}Si_{\sim 1}\rangle$, Nos. 46-48, 68, 129-134; $\langle Al_{\sim 2}Si_{\sim 2}\rangle$, Nos. 51-52; $\langle Al_{\sim 1\text{-}2}Si_{\sim 2\text{-}1}\rangle$, Nos. 55-62, 163; $\langle Al_{\sim 1}Ge_{\sim 3}\rangle$, Nos. 75, 78-79; $\langle Ge_{\sim 4}\rangle$, Nos. 71, 72-76; and $\langle Si_{\sim 4}\rangle$, Nos. 28, 65, 69-70, 73-74, 77, 80, 144 (see details in Appendix P).

Histograms displaying the distributions of basal and apical edge lengths, O_{bas}-T-O_{bas} and O_{bas}-T-O_{api} angles, and individual T-O bond lengths are presented in Figures 6.36, 6.37, and 6.38, respectively. For edge lengths and O-T-O angles, all three different values of a given type are included in a single distribution for each type. The main peaks appearing on all of these distributions correspond to the $\langle Al_{\sim 1}Si_{\sim 3}\rangle$ samples.

Clearly, apical edge (Figure 6.36) and O_{bas}-T-O_{api} (Figure 6.37) distributions are centred around larger values than basal edge and O_{bas}-T-O_{bas} ones. In fact, for 144 out of the 170 samples studied (≈85 %), all three values of apical edge lengths or O_{bas}-T-O_{api} angles in a given sample are larger than any of their basal counterparts. The few exceptions to this observation come from the following samples: a tetra-ferri-annite sample, No. 22; clintonite samples, Nos. 46-48, 68, 129-134; Rietveld-refined synthetic annite-syderophyllite samples, Nos. 55-62; the sample having the largest Ti-content in the tetrahedral sheet, No. 69 ($\langle Si^{4+}_{3.63}\ Al^{3+}_{0.02}\ Fe^{3+}_{0.035}Ti^{4+}_{0.305}\rangle$); a paragonite sample, No. 147; and two biotite samples, Nos. 19,145.

When apical edge lengths are larger than basal edge ones, it can be unambiguously concluded that the shapes of tetrahedrons are elongated with respect to an ideal tetrahedron (or compressed along the direction perpendicular to the elongation). However, one cannot ascribe that the elongation is caused by the larger size of the O_{bas}-T-O_{api} angles with respect to the O_{bas}-T-O_{bas} angles, because the elongation (or compression) also depends on bond lengths.

In examining the histograms showing the distributions of individual tetrahedral bond lengths (Figure 6.38), one sees that the apical (T-O3) bond length distribution is fairly similar to the three basal bond length distributions — namely (T-O1), (T-O2), and (T-O2'). The largest

difference is that $<Al_{-3}Si_{-1}>$, $<Al_{-1}Ge_{-3}>$, and $<Ge_{-4}>$ samples are more distinctively resolved on basal bond length distributions than on the apical one. Nonetheless, values of mean (<x>) and standard deviation (SD) of the sample population corresponding to each distribution of bond length are equal within error (Table 6.4). On the basis of the distributions of individual bond lengths and *O-T-O* angles, therefore, one might tentatively ascribe the elongation of tetrahedrons established above to be caused by an enlargement apical *O-T-O* angles at equal *T-O* bond lengths. However, as will be shown below, this is not usually the case.

Table 6.4 give values of mean (<x>) and standard deviation (SD) for each of the individual *T-O* distributions, as well as for various distributions that are discussed below.

Individual T-O bond lengths		
x	<x> (10^{-10} m)	SD (10^{-10} m)
(T-O1)	1.668(2)*	0.026(1)
(T-O2)	1.666(2)	0.028(1)
(T-O2')	1.668(2)	0.027(1)
(T-O3)	1.667(2)	0.029(2)
Sample-specific distortion parameters		
x	<x> (%)	SD (%)
100 [(T-O1)-$<T\text{-}O>_{bas}$] / $<T\text{-}O>_{bas}$	0.03(2)	0.23(1)
100 [(T-O2)-$<T\text{-}O>_{bas}$] / $<T\text{-}O>_{bas}$	-0.07(3)	0.38(2)
100 [(T-O2')-$<T\text{-}O>_{bas}$] / $<T\text{-}O>_{bas}$	0.04(3)	0.36(2)
100 [(T-O3)-$<T\text{-}O>_{bas}$] / $<T\text{-}O>_{bas}$	0.0(1)	1.28(7)
100 [(O1-O2)-$<O\text{-}O>_{bas}$] / $<O\text{-}O>_{bas}$	-0.07(4)	0.49
100 [(O1-O2')-$<O\text{-}O>_{bas}$] / $<O\text{-}O>_{bas}$	0.04(3)	0.43
100 [(O2-O2')-$<O\text{-}O>_{bas}$] / $<O\text{-}O>_{bas}$	0.03(1)	0.14
100 [(O3-O1)-$<O\text{-}O>_{api}$] / $<O\text{-}O>_{api}$	0.11(3)	0.38
100 [(O3-O2)-$<O\text{-}O>_{api}$] / $<O\text{-}O>_{api}$	-0.10(3)	0.44
100 [(O3-O2')-$<O\text{-}O>_{api}$] / $<O\text{-}O>_{api}$	-0.01(2)	0.31

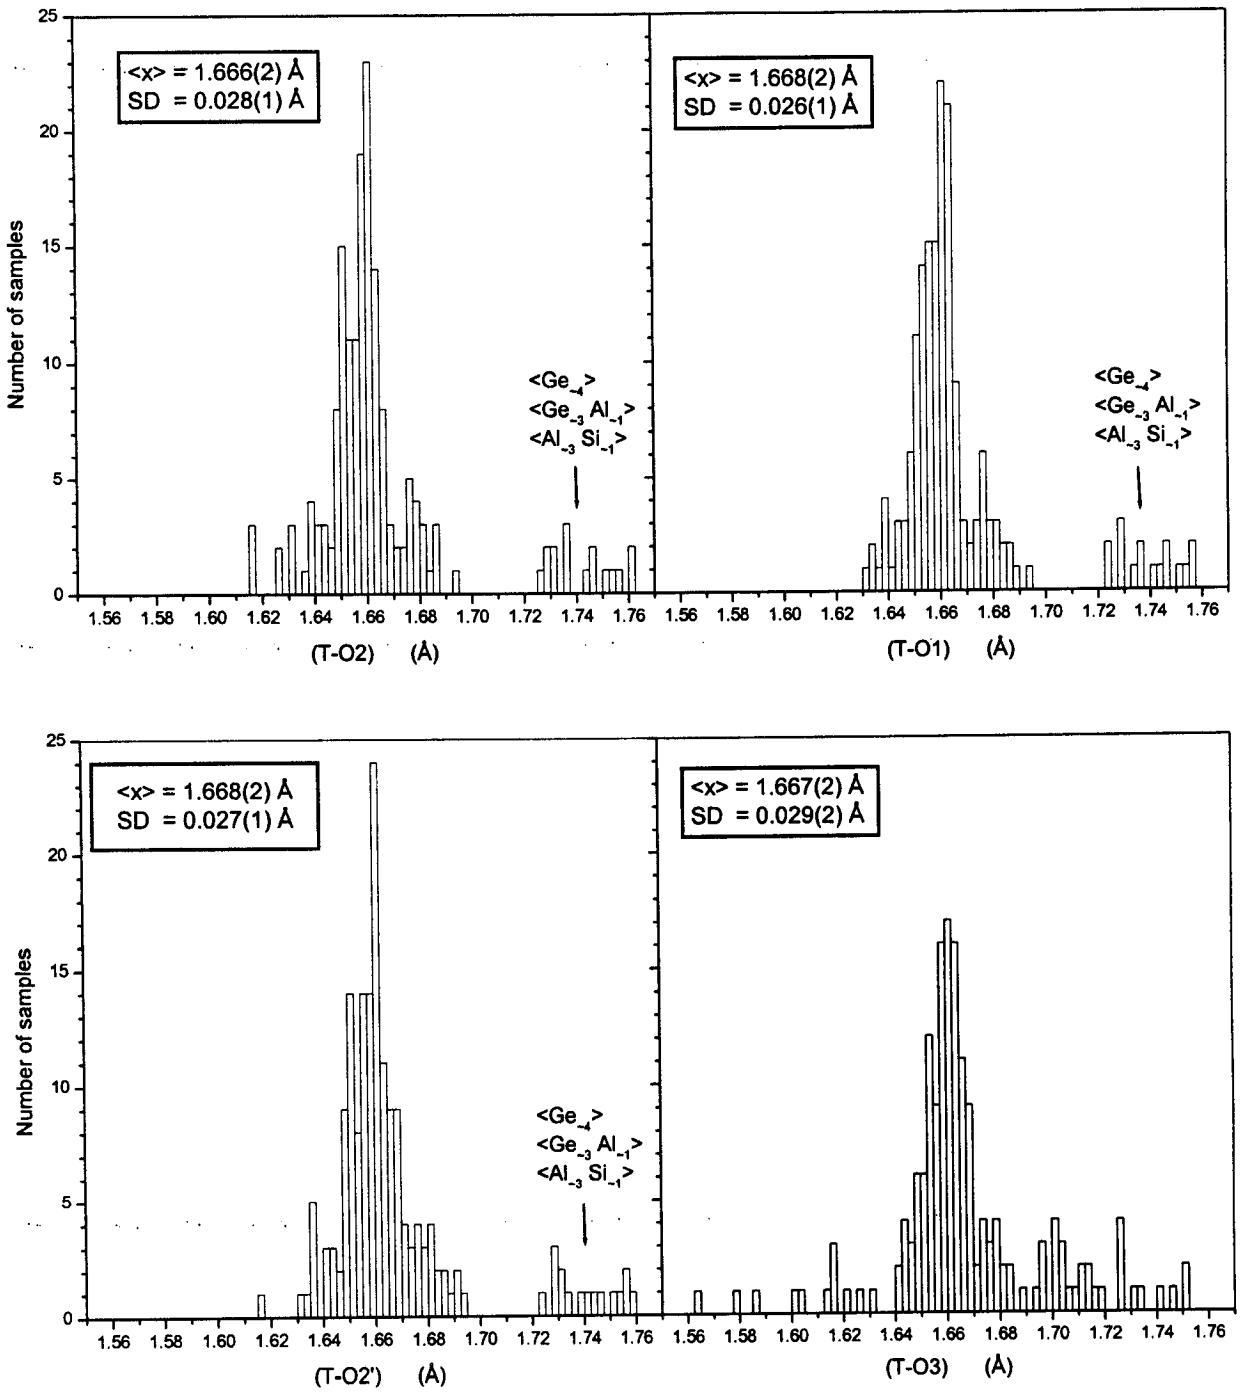

Figure 6.38. Histograms showing the distributions of individual *T-O* bond lengths.

In order to obtain structural information about tetrahedral distortions, distributions of the following sample-specific dimensionless individual bond length, edge length, and angle distortion parameters were investigated:

$$BLD_i = (100\ \%)\ [\ (T\text{-}O)_i - \langle T\text{-}O\rangle_{bas}\ ]\ /\ \langle T\text{-}O\rangle_{bas} \quad (6.39a)$$

$$ELD^{bas}{}_i = (100\ \%)\ [\ (O\text{-}O)_i - \langle O\text{-}O\rangle_{bas}\ ]\ /\ \langle O\text{-}O\rangle_{bas} \quad (6.39b)$$

$$ELD^{api}{}_i = (100\ \%)\ [\ (O\text{-}O)_i - \langle O\text{-}O\rangle_{api}\ ]\ /\ \langle O\text{-}O\rangle_{api} \quad (6.39c)$$

$$AD^{bas}{}_i = (100\ \%)\ [\ \tau_i - \langle\tau\rangle_{bas}\ ]\ /\ \langle\tau\rangle_{bas} \quad (6.39d)$$

$$AD^{api}{}_i = (100\ \%)\ [\ \tau_i - \langle\tau\rangle_{api}\ ]\ /\ \langle\tau\rangle_{api} \quad (6.39e)$$

In the above equations, the symbols have the following meanings: i) *i* refers to an individual bond length $(T\text{-}O)_i$, edge length $(O\text{-}O)_i$, or *O-T-O* angle τ_i; ii) τ is the symbol used herein below to designate an *O-T-O* angle; iii) $\langle\tau\rangle_{bas}$ is the average of the three O_{bas}-*T*-O_{bas} angles in a given tetrahedron of a given structure refinement of a given sample; iv) $\langle\tau\rangle_{api}$ is the average of the three O_{api}-*T*-O_{bas} angles in a given tetrahedron of a given structure refinement of a given sample; v) $\langle T\text{-}O\rangle_{bas}$ = [(T-O1)+(T-O2)+(T-O2')]/3 ; $\langle O\text{-}O\rangle_{bas}$ = [(O1-O2)+(O1-O2)+(O2-O2')]/3; and $\langle O\text{-}O\rangle_{api}$ = [(O3-O1)+(O3-O2)+(O3-O2')]/3. For Eq. 6.39b, only individual basal edge lengths were considered; and similarly so for Eqs. 6.39c-6.39e. Values of mean (<x>) and standard deviation (SD) for the distributions of parameters calculated from Eqs. 6.39 are compiled in Table 6.4.

In examining the BLD_i distributions (Eq. 6.39a) shown in Figure 6.39, the most striking feature is that the apical $BLD_{T\text{-}O3}$ distribution is unequivocally larger than any of the three basal BLD_i distributions. According to <x> and SD values (Table 6.4), all BLD_i distributions are centred around zero and the $BLD_{T\text{-}O3}$ distribution is approximately three to five times wider than the basal BLD_i distributions. Contrary to individual *T-O* bond length distributions (Figure 6.38), which suggested equal *T-O* bond lengths, Figure 6.39 clearly establishes that the apical (T-O3) bond length can differ significantly from the basal *T-O* bond lengths, in a given structure of a given sample. The $BLD_{T\text{-}O3}$ parameter is a direct measure of the extent to which this is the situation, provided that the basal *T-O* bond lengths are sufficiently close amongst each other.

Excluding a few outliers, the central peaks of the three basal BLD_i distributions are well constrained around zero (Figure 6.39). In fact, as indicated by values of <x> and SD given in Table 6.4, distributions of $ELD^{bas}{}_i$, $ELD^{api}{}_i$, $AD^{bas}{}_i$, and $AD^{api}{}_i$ parameters all behave similarly or have even smaller widths (not shown; except for $ELD^{bas}{}_i$, see Figure 6.46 below). To the extent that the population of 170 samples considered here is representative of the ensemble of possible

individual tetrahedral distortions occurring in 1*M* mica structures (and possibly layer silicates in general), this means that average tetrahedral distortion parameters $\langle T\text{-}O\rangle_{bas}$, $\langle O\text{-}O\rangle_{bas}$, $\langle O\text{-}O\rangle_{api}$, $\langle\tau\rangle_{bas}$, and $\langle\tau\rangle_{api}$ are valid indicators of tetrahedron shapes, with fractional sample specific deviations of at most ~0.1-0.5 % , except (T-O3) with 1.3 % (Table 6.4)

In order to illustrate the point made above, Figure 6.40 compares simple geometrical model predictions made from Eqs. 6.15-6.18 (Section 6.2.4) to average tetrahedral distortion parameters actually observed in the structures. The predictions are shown as solid lines, whereas data points come from values of $\langle T\text{-}O\rangle_{bas}$, $\langle\tau\rangle_{bas}$, $\langle\tau\rangle_{api}$, and h_t^{bas} tabulated in Appendix P. The parameter h_t^{bas} is the *euclidian* distance between the tetrahedral cation and the plane formed by the three basal oxygen atoms in a given tetrahedron, whose values were determined using analytic geometry formulae. Given the remarkable agreement of experimental data with predictions, it is concluded that simple geometrical models of ideal, iso-bond-basal-flattened, or aniso-bond tetrahedrons — which are all constructed using a rigid base formed by three basal *T-O* bonds having an equal length (see Section 6.2.4) — are valid representations of actual tetrahedrons found in trioctahedral-1*M* micas.

It is interesting to point out the evolution of sample compositions along the solid-line predictions shown in Figure 6.40. The combined charge per formula unit of interlayer and tetrahedral cations progressively increases from ~15+ to ~17+ as one goes from compressed — $\tau_{bas} > \tau_{ideal}$ ($\tau_{ideal} \approx 109.47°$) — to elongated — $\tau_{bas} < \tau_{ideal}$ — tetrahedrons. This is attributed to size of the cations that occupy both the tetrahedral and interlayer cations.

In contrast with the above noted distinct evolution of tetrahedron's shapes with compositions, a surprising feature is that the tetrahedron's height h_t[1] and the apical bond length (T-O3) do not evolve in the same manner as a function of $\langle\tau\rangle_{bas}$ (Figure 6.41). Excluding $\langle Ge_{-4}\rangle$ and $\langle Ge_{-3}Al_{-1}\rangle$ samples, (T-O3) increases somewhat regularly with $\langle\tau\rangle_{bas}$, extending over a range of ~12.0 % around its mean ($\langle T\text{-}O3\rangle$ = 1.667(2) Å; see Table 6.4), whereas h_t does not apparently vary in a manner that is related to $\langle\tau\rangle_{bas}$, remaining ~4.5 % around its mean ($\langle h_t\rangle$ = 2.247(3) Å; see Figure 6.41). This situation is paradoxical: the apical bond length increases as tetrahedrons are compressed (i.e. as $\langle\tau\rangle_{bas}$ increases), whereas the height of the tetrahedrons stays approximately the same whether the tetrahedrons are elongated or compressed. This strange behaviour will be rationalized below.

In addition to a tetrahedral flattening via τ angles (i.e. elongation or compression) and to

---

[1] Values of h_t reported in Appendix P were determined using analytic geometry formulae; in a given tetrahedron, h_t is the distance between the apical O3 oxygen atom and the plane formed by the three basal oxygen atoms.

a frequent difference in length between apical and basal bonds, there are two additional tetrahedral distortions that occur.

One of these distortions is pointed out here for the first time. It consists of a bending that makes the apical (T-O3) bond with respect to the pyramidal base formed by the three basal *T-O* bonds. In a given tetrahedron, this distortion is conveniently measured by the angle η between a line given by the direction of the (T-O3) bond and a line running from tetrahedral cation *T* to the geometric centre of the triangle formed by the three basal edges (Figure 6.42a). In an ideal, iso-bond-basal-flattened or aniso-bond tetrahedron, $\eta = 180^{\circ}$.

The other distortion is referred to as tetrahedral corrugation [Brigatti & Guggenheim 2002]. This distortion manifests itself as an out-of-plane twisting of the basal *O*2 oxygen atoms located in the [110] tetrahedral chains (Figure 6.42b), determining a departure from coplanarity of the basal triangle formed by the three basal edges. Basal-oxygen plane corrugation is determined by the parameter Δz :

$$\Delta z = \left(O1z - O2z\right) \cdot c \sin\beta \quad . \tag{6.40}$$

Figure 6.42 presents the distributions of Δz and $\left(180^{\circ} - \eta\right)$ found in 1*M* structures, along with an illustration of the degree of correlation between these two parameters (Table 6.5). A positive value of η was given if $O1z > O2z$, and vice versa for negative η values. Although the correlation is affected by the presence of a few outliers, a definite trend can be discerned. There now remains to establish the nature of the link between two distortions.

[Lee & Guggenheim 1981] demonstrated that the corrugation of the basal oxygen atom plane Δz is related to differences in distance between apical oxygen atoms linked to octahedrons of different size. In a recent study covering more than 200 mica structures (146 trioctahedral and 55 dioctahedral), [Brigatti & Guggenheim 2002] have also confirmed that there exits such a relationship by plotting Δz as a function of the maximum difference in octahedral bond length between the two octahedral sites having the largest and smallest average bond lengths in a given structure, i.e. $[\langle M\text{-}O\rangle_{max} - \langle M\text{-}O\rangle_{min}]$. In light of results presented in Section 6.3.2, Figure 6.44 displays Δz as a function of the normalized squared size difference $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$ (see Eq. 6.37); similar correlations are found if the difference $[\langle M1\text{-}O\rangle - \langle M2\text{-}O\rangle]$ is considered instead (Table 6.5). Given the similar results that the above independent investigations have yielded, therefore, it appears evident that octahedral size differences play an important role in tetrahedral corrugation.

It shall now be demonstrated that the origin of tetrahedral plane corrugation can be

understood in terms of geometrical considerations associated to the matching of a tetrahedral sheet to a geometric meso-octahedral sheet and that this explains the correlation illustrated in Figure 6.44.

Consider the two in-plane (001) projections shown in Figure 6.45, which both display a tetrahedral sheet fitting on top of a geometric meso-octahedral sheet. Certain elements are common to both top and bottom diagrams: i) the basal edges of the tetrahedrons (solid lines) are drawn as coplanar triangular basal faces rotated by a specified α, which are attached to a geometric homo-octahedral sheet having certain lateral *a* and *b* dimensions (with $b = \sqrt{3} \cdot a$, following Section 6.1) ii) the apical O3 oxygen atoms (filled circles) are placed at positions corresponding to a geometric meso-octahedral sheet having $d_{M1} > d_{M2}$ and the same *a* and *b* as the overlying tetrahedral sheet; and iii) the thicker solid lines designate the basal edges (O2-O2') that lie along the *a*-axis direction.

Focus first on the top diagram (Figure 6.45). In this case, the apical edges of the tetrahedrons (dashed lines) are shown as if they belonged to ideal, iso-bond or aniso-bond tetrahedrons, that fit on top a geometric homo-octahedral sheet. In such a situation, one sees that when the three basal edges of a given tetrahedron are coplanar, then, in any given tetrahedron, there is a lateral shift $\vec{\Delta}$ between the position of the geometric centre of the basal triangular face — which is also the position of the apical oxygen atom in a homo-octahedral sheet — and the position of the apical oxygen atom belonging to the meso-octahedral sheet. of the bottom diagram.

Consider now the bottom diagram (Figure 6.45), where the $\vec{\Delta}$ vectors are indicated by a tiny arrow sign on each tetrahedron. In this case, each apical edge links one of the three basal oxygen atoms to an apical O3 atom belonging to the geometric meso-octahedral sheet. If the basal edges are coplanar, then one can clearly see that the three apical edges must have different lengths. In a tetrahedron of such shape, moreover, if a cation *T* is placed at a point equidistant from its four coordinating oxygen atoms (or at any points where the three basal *T-O* bond lengths are equal), then one must have that $\eta \neq 180^{\circ}$ (Figure 6.42a). From the developments made in this paragraph, one concludes that unless tetrahedrons were severely distorted beyond what is observed, a tetrahedral sheet comprised of coplanar basal equilateral triangular faces cannot fit on top of a geometric meso-octahedral sheet.

In examining Figure 6.45 more closely, one can appreciate that a straightforward means to regularize the tetrahedrons' shapes is to incline the basal faces in directions given by the $\vec{\Delta}$ vectors. Without changing the *a* and *b* dimensions, an effective way to accomplish this task is through an adjustment of the *z*-coordinates of the O1 atoms, keeping the O2 atoms fixed, which

immediately leads to tetrahedral corrugation, and to unequal basal edge lengths. If the O1 atoms are also allowed to move laterally in a direction parallel to *a* (i.e. along the [110] direction), then both apical and basal edges can more closely equalize their lengths amongst each other, with the end result that the shape of each tetrahedron is more regular and that a more typical tetrahedral bonding symmetry is recovered for each cation *T*.

The logical reasoning undergone in the above treatment sheds light on a few issues pertaining to the crystal chemistry of 2:1 layer silicates. First, a tetrahedral sheet composed of tetrahedrons having a simple geometrical shape (be it ideal, iso-bond, or aniso-bond) cannot be arranged to match a geometric meso-octahedral sheet. This, therefore, is a fundamental limit of simple geometrical models. That is, the usual (stretched, expanded, flattened, counter-rotated, rotated) regular coordination polyhedra (octahedrons and tetrahedrons) cannot be assembled such that the tetrahedral and octahedral sheets match in a geometric meso-octahedral 2:1 layer silicate (i.e., one with <M1-O> ≠ <M2-O>).

Another finding is that tetrahedral corrugation is particularly favourable. From a network point of view, corrugation is economical: it does not change the lateral *a* and *b* dimensions, it does not alter the connectivity of the bonds, and it only requires a unidimensional displacement of one single atomic site in the crystal structure. Corrugation can therefore be viewed as the favoured non-planar cooperative response of the tetrahedral sheet to the presence of a meso-octahedral sheet, which arises under the driving influence of strong *T-O* bonds wanting to stabilize at similar lengths in a regular tetrahedral bonding symmetry.

In comparing the SD values obtained for distributions of sample-specific distortion parameters compiled in Table 6.4, one notes an increasing trend that will now be explained. Most notably, (O2-O2') basal edges give the thinnest of not only all ELD^{bas}_{i} distributions (Figure 6.46), but also all other sample-specific distortion parameters considered. Then come the SD values of the distributions of $BLD_{T\text{-}O1}$ and $AD^{bas}_{O2\text{-}T\text{-}O2'}$ parameters, which are followed by the other two basal BLD_{i} distributions, essentially reflecting the fact that basal *T-O* bonds always equilibrate at similar lengths. The rest of the SD values obtained for distributions of ELD^{api}_{i}, the other two AD^{bas}_{i}, and AD^{api}_{i} parameters are all equal or larger than those previously mentioned, in accordance with the idea that individual bond length, edge length, and angle distortions taking place within a single tetrahedron are consequences of the tetrahedrons being corrugated as a result of the presence of geometric meso-octahedral sheets.

The significantly larger distribution of the $BLD_{T\text{-}O3}$ parameter can be understood as follows. Each O3 atom is constrained by bonding to three octahedral cations (in the trioctahedral case) that are usually not the same whereas the tetrahedral basal oxygen atoms have no such

strong covalent bonding constraints. This may explain why the $BLD_{T\text{-}O3}$ parameter is not correlated with any other distortion parameters such as $[\langle M1\text{-}O\rangle^2-\langle M2\text{-}O\rangle^2]/a^2$, $(180^\circ-\eta)$, Δz, or α (see Table 6.5).

Finally, Figure 6.47 demonstrates that the lateral extension of the tetrahedral sheets of trioctahedral-1*M* micas can always be accounted for in terms of simple geometrical models via Eq. 6.19 (Subsection 6.2.5). In the above results, it was shown that the average basal edge length $\langle O\text{-}O\rangle_{bas}$ is virtually always equal to the length of the basal (O2-O2') edges located along the [110] tetrahedral chains (Figure 6.46). The case of the only exception, norrishite sample No. 80, is due to a break of the $b = \sqrt{3}a$ pseudo-hexagonal symmetry (see Section 6.1).

In a given 1*M* structure, Figure 6.48 shows that the tetrahedral rotation can be evaluated using two different methods: i) by the average tetrahedral rotation angle α,

$$\alpha = \sum_{i=1}^{6} \alpha_i \quad , \tag{6.41}$$

where $\alpha_i = |120\text{-}\phi_i|$ and where ϕ_i is one of the six different angles between basal edges of neighbouring tetrahedrons articulated in the tetrahedral rings of a 1*M* structure; or ii) by the angle $\alpha_{(O2\text{-}O2')\text{-}[110]}$ that makes the basal (O2-O2') edges with respect to the *a*-axis direction,

$$\alpha_{(O2\text{-}O2')\text{-}[110]} = \arctan\left[\sqrt{3}(1-4\cdot O2y)\right]. \tag{6.42}$$

Figure 6.48 illustrates the extent to which the above point is valid; the only exceptions are Rietveld-refined synthetic samples (Nos. 55-62) and samples for which the R-values are relatively high.

In conclusion, whereas simple geometrical models cannot provide the exact positions of each atom within a given tetrahedron due to the presence of meso-octahedral sheets in *2:1* layer silicates, the lateral extension of the tetrahedral sheets can be accurately predicted from simple geometric considerations despite local distortions actually occurring in individual tetrahedrons.

6.3.4 Interlayer site distortions

Figures 6.49, 6.50, and 6.51 show individual distances as functions of average lengths for the following quantities, respectively (see Table 6.3 for symbols and nomenclature): i) individual inner interlayer site bond lengths $(A\text{-}O1)_{in}$ and $(A\text{-}O2)_{in}$ as functions of the average inner interlayer site bond length $\langle A\text{-}O\rangle_{in}$ (= 1/6·[2·(A-O1) + 4·(A-O2)]); ii) individual basal inner interlayer edge lengths $(O1\text{-}O2)^{bas}_{in}$ and $(O2\text{-}O2)^{bas}_{in}$ as functions of the average basal inner interlayer edge length $\langle(O\text{-}O)^{bas}\rangle_{in}$ (=1/6·[4·$(O1\text{-}O2)^{bas}_{in}$ + 2·$(O2\text{-}O2)^{bas}_{in}$]); and iii) individual lateral inner interlayer edge lengths $(O1\text{-}O2)^{lat}_{in}$ and $(O2\text{-}O2)^{lat}_{in}$ as a function of the average lateral inner interlayer edge length $\langle(O\text{-}O)^{lat}\rangle_{in}$ (=1/6·[4·$(O1\text{-}O2)^{lat}_{in}$ + 2·$(O2\text{-}O2)^{lat}_{in}$]). In addition, Figures 6.49-6.51 present histograms displaying the distributions of normalized size differences (100%)[$(A\text{-}O1)_{in}$ - $(A\text{-}O2)_{in}$]/$\langle A\text{-}O\rangle_{in}$, (100%)[$(O1\text{-}O2)^{bas}_{i}$ - $(O2\text{-}O2)^{bas}_{in}$]/$\langle(O\text{-}O)^{bas}\rangle_{in}$, and (100%)[$(O1\text{-}O2)^{lat}_{in}$ - $(O2\text{-}O2)^{lat}_{in}$]/$\langle(O\text{-}O)^{lat}\rangle_{in}$, respectively.

Histograms displaying the distributions of *A-O* bond lengths and interlayer distances d_{int} are presented in Figure 6.52, whereas the distributions of basal and lateral inner interlayer edge lengths are given in Figure 6.53. For bond and edge lengths, the two different values of a given type (basal or lateral) are included in a single distribution for each type. The main peaks appearing on all of these distributions correspond to the $\{K^{1+}\}$ samples.

The interlayer distance d_{int} is the thickness of the interlayer region calculated from the z coordinates of basal oxygen atoms (compiled in Appendix P) as:

$$d_{int} = 2 \cdot c \sin\beta \cdot \left(1/3 \cdot \left[O1z + 2 \cdot O2z\right]\right) . \tag{6.43}$$

Values of d_{int} and all quantities plotted in Figures 6.49-6.53 are tabulated in Appendix P.

As is well known (e.g., see [Brigatti & Guggenheim 2002]), Figures 6.49-6.53 demonstrate that inner interlayer site bond lengths, basal and lateral edge lengths, and interlayer distances fall into separate groups that depend on the chemical composition of the interlayer sites: $\{K^{1+}_{-1}\}$, $\{Na^{1+}_{-1}\}$, $\{Ca^{2+}_{-1}\}$, and $\{Cs^{1+}_{-1}\}$.

In examining the distributions of normalized size differences (100%)[$(A\text{-}O1)_{in}$ - ($A\text{-}O2)_{in}$]/$\langle A\text{-}O\rangle_{in}$, (100%)[$(O1\text{-}O2)^{bas}_{in}$ - $(O2\text{-}O2)^{bas}_{in}$]/$\langle(O\text{-}O)^{bas}\rangle_{in}$, and (100%)[$(O1\text{-}O2)^{lat}_{in}$ - ($O2\text{-}O2)^{lat}_{in}$]/$\langle(O\text{-}O)^{lat}\rangle_{in}$ shown in Figures 6.49-6.51, one notes that excluding a few outliers, all distributions are well constrained around zero, with fractional sample-specific deviations of at most only ~0.5-0.7 % for each distribution. This means that the shapes of inner interlayer site octahedrons can be adequately given from the average geometric parameters $\langle A\text{-}O\rangle_{in}$,

$<(O\text{-}O)^{bas}>_{in}$, and $<(O\text{-}O)^{lat}>_{in}$.

Another important distortion parameter is the inner interlayer octahedron flattening angle ϕ_{in} , that can be obtained from either: i) the average inner interlayer site bond length $<A\text{-}O>_{in}$ and the interlayer distance d_{int} via Eq. 6.24 (Subsection 6.2.6),

$$\phi_{in} = \arccos\left[\frac{d_{int}/2}{<A-O>_{in}}\right] \quad ; \tag{6.44}$$

or ii) the average basal $<(O\text{-}O)^{bas}>_{in}$ and lateral $<(O\text{-}O)^{lat}>_{in}$ inner interlayer edge lengths via Eq. 6.6 (Subsection 6.2.1),

$$\phi_{in} = \arcsin\sqrt{\frac{4}{3\left(1+\left[\frac{<(O-O)^{lat}>_{in}}{<(O-O)^{bas}>_{in}}\right]^2\right)}} \quad . \tag{6.45}$$

In the $1M$ structural refinements that were investigated, values of ϕ_{in} obtained from Eqs. 6.44 and 6.45 are equal to each other to within $\pm 0.02°$; both of these ϕ_{in} values are compiled in Appendix P.

Let us now look into the matching of interlayer site octahedrons to tetrahedral sheets. Figure 6.54 compares observed interlayer distances d_{int} to predictions made from Eq. 6.25 (Subsection 6.2.6) using the values compiled in Appendix P for the lattice parameter a , the average inner interlayer bond length $<A\text{-}O>_{in}$,the average basal tetrahedral edge length $<O\text{-}O>_{bas}$, and the average tetrahedral rotation angle α (as defined in Eq. 6.41, Subsection 6.3.3). The solid lines that are drawn in Figure 6.55 correspond to a 1:1 correspondence between the x and y axes of each graph. Given the remarkable agreement between theoretical and observed values of d_{int} , therefore, Figure 6.54 clearly demonstrates that when all relevant crystal chemical parameters are properly taken into account via Eq. 6.25, simple geometrical models of tetrahedrons and inner interlayer octahedrons are sufficient to explain the matching of tetrahedral sheets to interlayer octahedrons. The case of the only notable exception, norrishite sample No. 80, is due to a break of the $b = \sqrt{3}a$ relationship (see Section 6.1).

The fact that all relevant crystal chemical parameters are necessary is emphasized in Figure 6.55, where the evolutions of the interlayer distance d_{int} and the inner interlayer octahedron flattening angle ϕ_{in} are plotted as functions of the average tetrahedral rotation angle α . The lines (solid, dashed, or dotted) that are shown in Figure 6.55 correspond to predictions made on the

basis of Eq. 6.25b (Subsection 6.2.6), which specifies that the position of a given line depends on the particular values of inner interlayer octahedron bond length, $(A\text{-}O)_{in}$, and tetrahedral basal edge length, e_t^{bas}, that are assumed. All together, Figure 6.55 allows one to visualize that at a fixed $(A\text{-}O)_{in}$ interlayer bond length, when the basal tetrahedral triangular faces rotate by α due to an increase of the basal edge length e_t^{bas}, then the interlayer distance d_{int} increases via the flattening angle ϕ_{in} of the inner interlayer octahedron. That is, as the tetrahedral rings close up, the interlayer cations move away from the tetrahedral sheets.

In Figure 6.55, we now focus on the $\{K^{1+}\}$ samples. If the basal tetrahedral edge length e_t^{bas} is constrained to a range of values between 2.67 and 2.72 Å — that is consistent with the variation of basal edge length values observed for these samples (see samples labelled as $<Al_{\sim 1}Si_{\sim 3}>$ in Figure 6.36, Subsection 6.3.3) — then in order to cover the full range of observed values for d_{int} or ϕ_{in}, one needs to vary $(A\text{-}O)_{in}$ from 3.05 to 2.90 Å. From a crystal chemistry perspective, one expects a cation in octahedral coordination to have a specific bond length, especially within a given type of network. In the present case, however, the extent of the inner interlayer octahedral bond length variation for K^{1+} is estimated at ~5.0 % (=100[3.05 - 2.90]/2.975) for the $<Al_{\sim 1}Si_{\sim 3}>\{K_{\sim 1}\}$ samples. By contrast, the basal edge length variation is of only ~1.8 % (=100[2.72 - 2.67]/2.695) for the same group of samples, despite the effect that sample-to-sample differences in Al:Si ratios within this group exert on tetrahedral sheets' dimensions.

In view of the above considerations, the immediate question to ask is: What could be the origin of such a large bond length variation for the K^{1+} cation in trioctahedral micas ? Useful insights into this situation is offered by considering the interatomic distance (A-O4) between the interlayer *A* cation and the O4-site anion. The O4 anion is the OH/F/Cl anion of the octahedral sheet, that is directly above and below the interlayer cation.

Figure 6.56 displays the average inner interlayer bond length $<A\text{-}O>_{in}$, the interlayer distance d_{int}, and the lattice parameter *c* as functions of the (A-O4) distance. The dashed lines drawn in Figure 6.56 are linear regressions through the data. Different clusters of samples can be identified depending on the chemical composition of the interlayer sites, except for Rietveld-refined (Nos. 55-62) and Ge-containing (Nos. 71-72, 75-76, 78-79) samples which stand out separately. As indicated by the R-values of the fits, positive correlations with (A-O4) can be discerned for both *c* and d_{int}, while in the case of $<A\text{-}O>_{in}$, there might be a slight negative correlation. If the large variation of bond lengths for the K^{1+} cations were due to interactions between interlayer *A* cations and O4-site anions, then it is reasonable to believe that signs of this would be reflected in a behaviour dependent on the (A-O4) distance. This is precisely the case

here: irrespective of the exact nature of the interaction between the interlayer *A* cations and the O4 site anions, Figure 6.56 gives reasonable evidence that the (A-O4) distance is a key factor determining the length of the *c*-axis and the interlayer distance d_{int} , for a given identity of interlayer *A* cation.

Although half of d_{int} contributes to the (A-O4) distance along *c** (i.e., these two parameters are geometrically related one to another), the physical mechanisms contributing to each of these interatomic distances are quite distinct: the interlayer distance d_{int} follows from the bonding of the interlayer cations with the basal oxygen atoms that are part of the tetrahedral sheets (Figures 6.54 and 6.55), whereas the (A-O4) distance is a consequence of both interactions between the interlayer *A* cation and the O4 anion and the geometry of the T-O-T network. In any case, the (A-O4) distance is a convenient crystal chemical parameter to consider.

That being said, if the length of the *c*-axis predominantly depends on the character of the *A*-O4 interaction and on the type of interlayer cation, then it should not be much affected by the cationic species contained in the tetrahedral and octahedral sheets. Indeed, this is shown in Figure 6.57, where the *c* lattice parameter is plotted as a function of the interlayer distance d_{int}, as well as a function of the overall *T-O-T thickness*[1] , the latter quantity being a measure of the intralayer distance along *c** between the average positions of two basal-oxygen planes that comprise the octahedral sheet and the two tetrahedral sheets (values of *T-O-T thickness* are compiled in Appendix P). Whereas a clear relationship (R = 0.882) is exhibited between *c* and d_{int}, one can see that no net relation (R = 0.299) exists between the *c*-axis length and the *T-O-T thickness*. Given that *c* and d_{int} are also related to the (A-O4) distance (Figure 6.56), therefore, in the ensemble of trioctahedral-1*M* mica samples considered here, it clearly appears that the interaction between the interlayer *A* cation and the O4-site anion effectively controls the *c*-axis length, rather than being determined by the cationic species contained in the octahedral and tetrahedral sheets, for a given interlayer cation species.

There now remains to establish the nature of the physical mechanisms responsible for the behaviours observed in Figures 6.56 and 6.57, that should also explain the large bond length variation noted in Figure 6.55 for the K^{1+} cation in trioctahedral micas. Fortunately, as was reported in [Rancourt *et al.* 2001], enlightening leads into this situation are given by the lattice parameters of synthetic samples studied in this thesis.

In Figure 6.58, *c* is plotted *versus a* for all synthetic samples (refer to Table 3.1 for

---

[1]The *T-O-T thickness* was determined from the z coordinates of basal oxygen atoms and is equal to:

$$c \sin\beta \, [1 - 2/3 \cdot (O1z + 2 \cdot O2z)] .$$

nomenclature of the various solution series; consult Section 5.2 or Appendix W for values of the lattice parameters); for the sake of comparison, values of *c versus a* for single-crystal structure refinements are shown in Figure 6.59. In synthetic samples, for a given tetrahedral-site composition, one can see that although *a* varies as expected with the average octahedral radius (as does *b*, by virtue of the $b = \sqrt{3} \cdot a$ relationship explained in Section 6.1), *c* is relatively constant within a given solid solution for all series that have near-saturation amounts of structural OH groups. Figure 6.58, therefore, gives strong evidence that the above interpretation of Figures 6.56 and 6.57, in terms of a *c*-axis length being controlled by the nature of the *A*-O4 interaction rather than by the cationic species contained in the *2:1* layers, is correct. In addition, Figure 6.58 convincingly demonstrates that the presence of structural OH *versus* F in the O4-site is a crucial factor determining *c*.

Figure 6.60 separately shows the evolutions of the *c* lattice parameters for the annite-fluoroannite (Ann-FAnn) and the annite-oxyannite-ferrioxyannite (oxidized) series (Table 3.1) as functions of the nominal F content [X_F] and the heat-treatment temperature T_{TR}, respectively (consult Section 3.2 for details of the sample synthesis and heat-treatment conditions). Although the overall differences in the magnitude of *c* are similar in both series (~0.20 Å for oxidized; ~0.21 Å for Ann-FAnn), the most striking feature is the discontinuity in *c* that takes place in the oxidized samples between treatment temperatures T_{TR} = 350 and 370°C.

As explained in [Rancourt *et al.* 2001], the abrupt change in behaviour seen in the oxidized samples is interpreted as a *pillaring collapse* transition that occurs near the point where the OH concentration becomes zero as oxidation proceeds. Moreover, the gradual pre-transition decrease in *c* can be tentatively attributed to progressive OH-dipole bending away from the *c* axis, as more and more of the electrostatic interlayer compressional force is countered by fewer and fewer OH groups (whose protons oppose the K^{1+} interlayer cations). Such bending is consistent with the fact that, as the Fe^{3+}/Fe^{2+} ratio (Table 3.3) increases with the samples being oxidized more and more, a larger and larger fraction of the remaining OH groups see $^{[6]}Fe^{2+}$-$^{[6]}Fe^{2+}$-$^{[6]}Fe^{3+}$ or $^{[6]}Fe^{2+}$-$^{[6]}Fe^{3+}$-$^{[6]}Fe^{3+}$ nearest-neighbour configurations, rather than the dominant $^{[6]}Fe^{2+}$-$^{[6]}Fe^{2+}$-$^{[6]}Fe^{2+}$ configuration of the unoxidized starting IKO-Ann sample [Gilkes *et al.* 1972a, 1972b].

Before we end this subsection, it is important to state that tetrahedral corrugation does not affect any of the conclusions reached above regarding the inner interlayer *A* octahedron. This can be easily visualized by drawing the actual distortions that occur in the interlayer as a result of tetrahedral corrugation (not shown).

In conclusion, the results presented in this subsection can be summarized as follows: i) the interlayer site distortions can be adequately modelled using an iso-bond flattened octahedron;

ii) the matching of interlayer octahedrons to tetrahedral sheets is fully understood in terms of simple geometrical models via Eq. 6.25 (Subsection 6.2.4); iii) a large bond length variation is observed for K^{1+} in trioctahedral-1*M* micas; iv) the *c*-axis length is controlled by the nature of O4-site anion and its interaction with the interlayer *A* cation; and v) the large bond length variation for K^{1+} can be understood as arising from *A*-O4 interactions, which depend on the degree of OH-dipole bending away from the *c* axis introduced by M^{3+} to M^{2+} cationic substitutions in the octahedral sheets and on the degree of OH/F and OH/Cl substitutions.

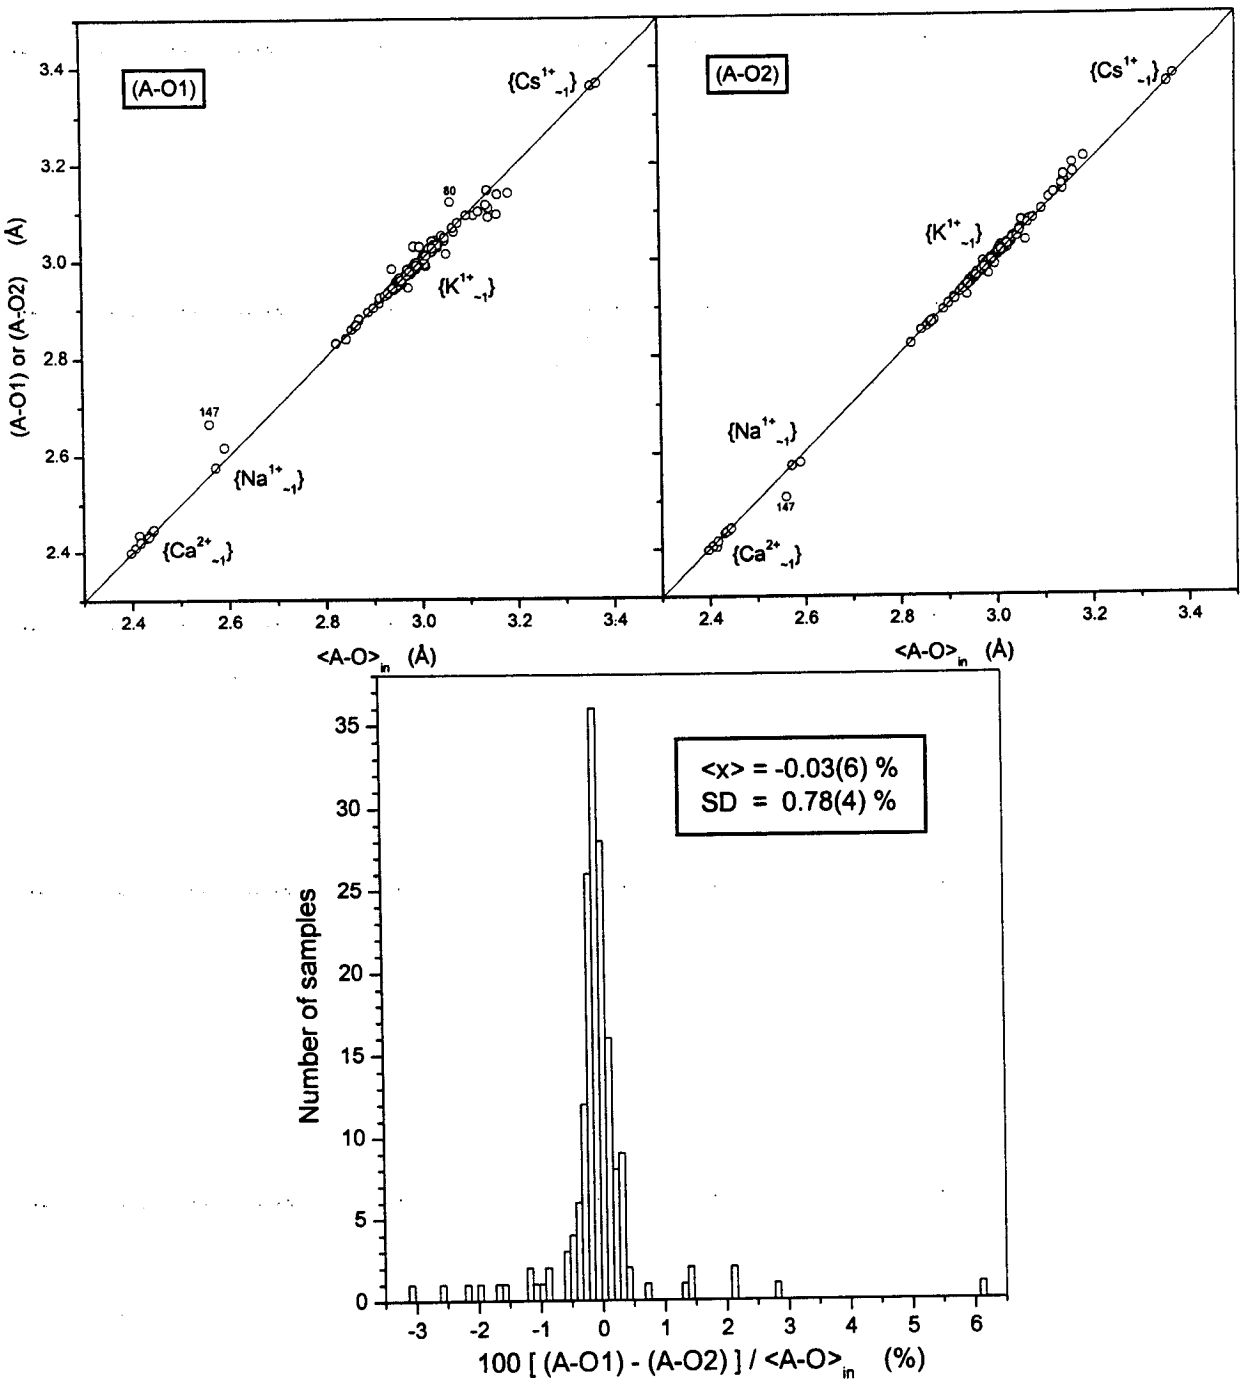

Figure 6.49. Evolution of individual inner *A-O* distances $(A\text{-}O1)_{in}$ and $(A\text{-}O2)_{in}$ as a function of the average inner interlayer site bond length $\langle A\text{-}O\rangle_{in}$ (=1/6·[2·(A-O1)+4·(A-O2)]). The solid lines that are shown represent a 1:1 correspondence between the *x* and *y* axes. A histogram displaying the distribution of the normalized size difference between the two inner *A-O* distances, (100 %) $[(A\text{-}O1)_{in} - (A\text{-}O2)_{in}] / \langle A\text{-}O\rangle_{in}$, is also shown.

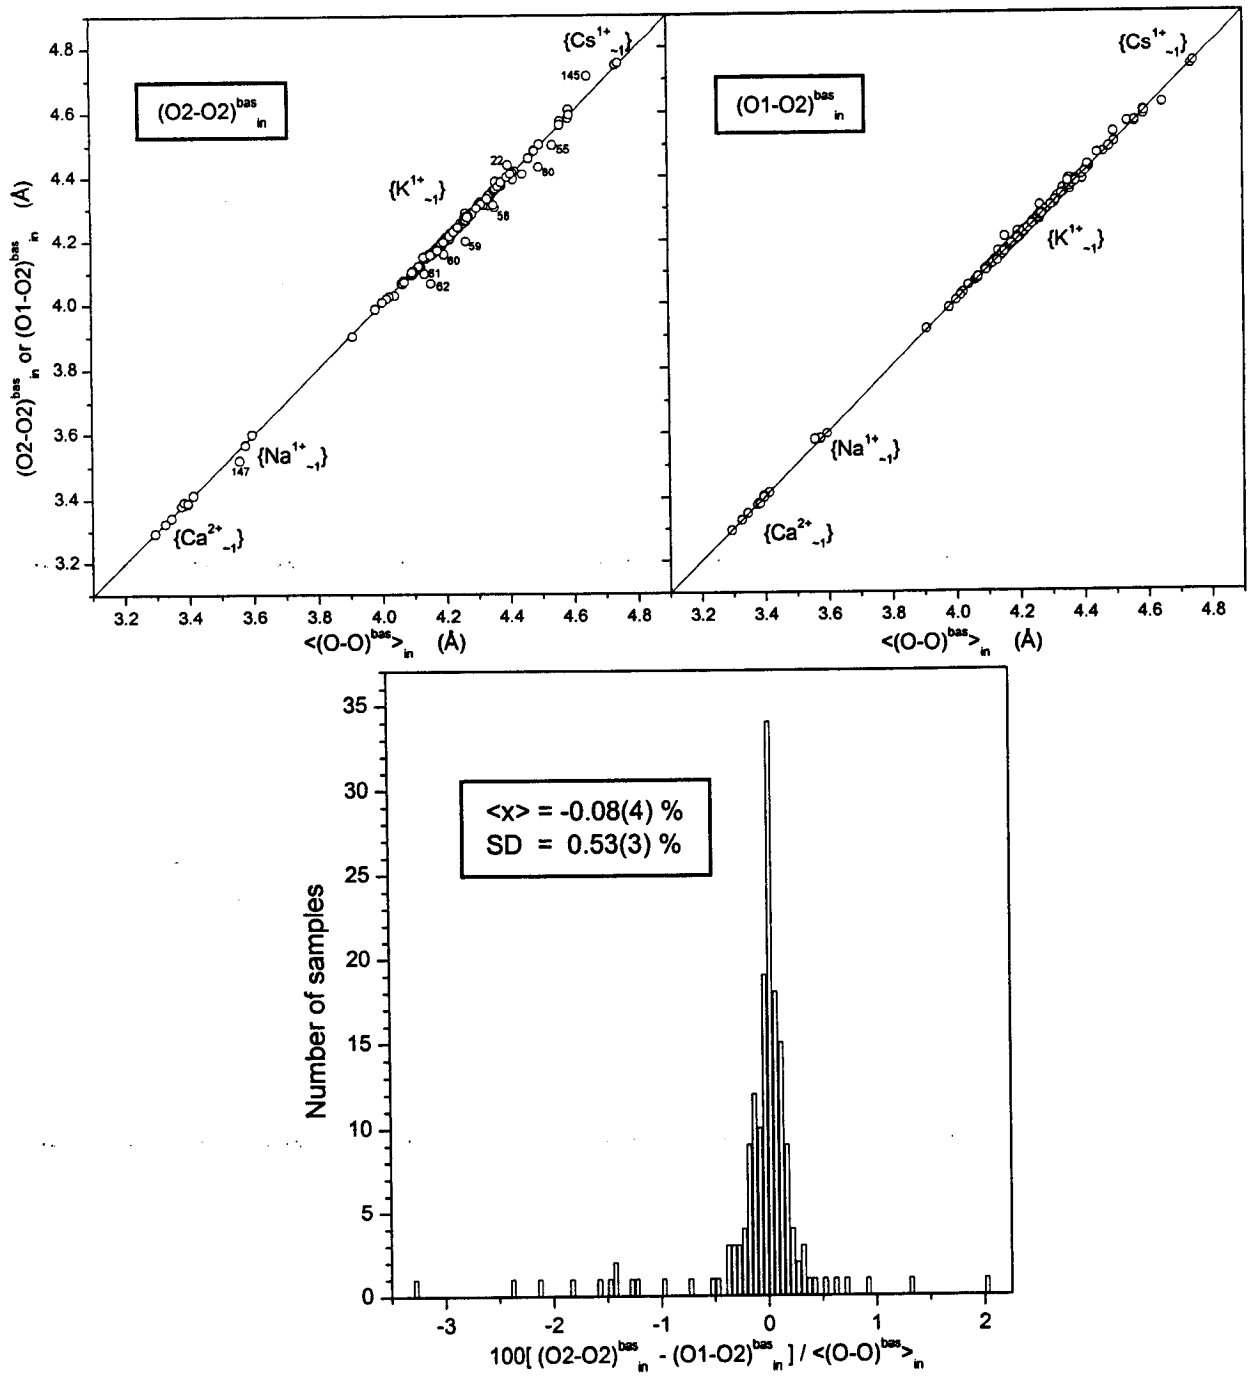

Figure 6.50. Evolution of basal inner interlayer edge lengths $(O1\text{-}O2)^{bas}_{in}$ and $(O2\text{-}O2)^{bas}_{in}$ as a function of the average basal inner interlayer edge length $\langle(O\text{-}O)^{bas}\rangle_{in}$ $(=1/6\cdot[4\cdot(O1\text{-}O2)^{bas}_{in} + 2\cdot(O2\text{-}O2)^{bas}_{in}])$. The solid lines that are shown represent a 1:1 correspondence between the *x* and *y* axes. An histogram displaying the distribution of the normalized size difference between the two inner basal distances, (100 %) $[(O1\text{-}O2)^{bas}_{in} - (O2\text{-}O2)^{bas}_{in}] / \langle(O\text{-}O)^{bas}\rangle_{in}$, is also shown.

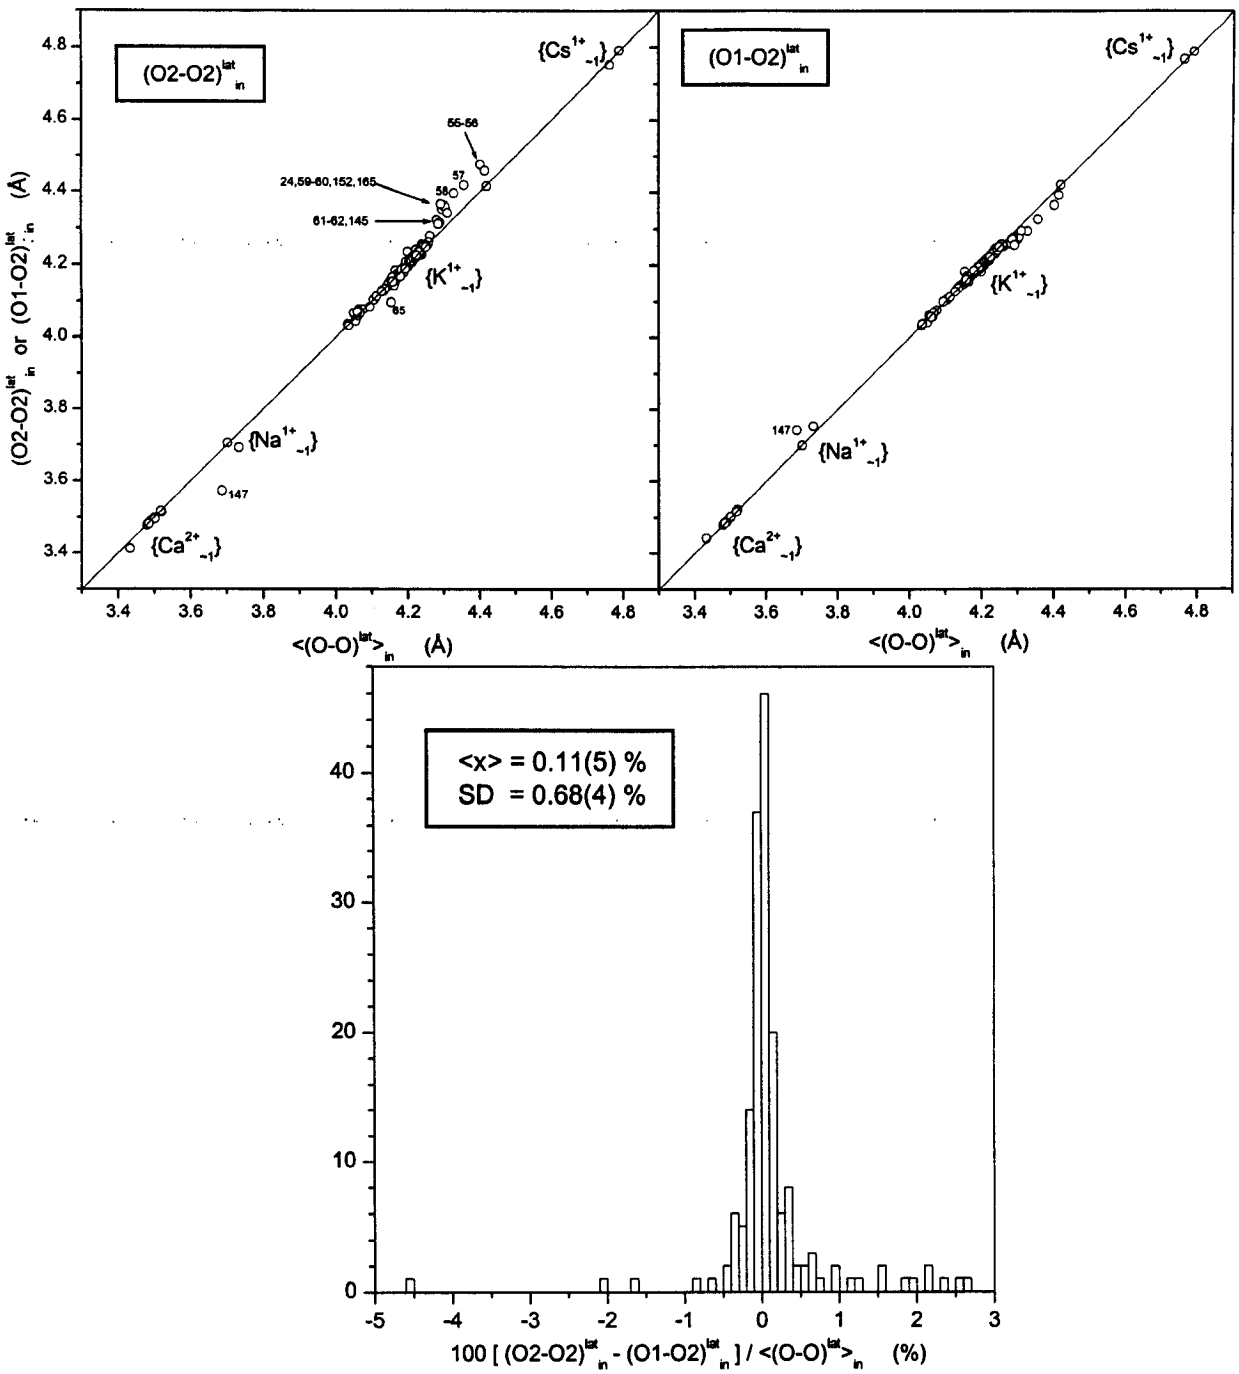

Figure 6.51. Evolution of lateral inner interlayer edge lengths $(O1\text{-}O2)^{lat}_{in}$ and $(O2\text{-}O2)^{lat}_{in}$ as a function of the average lateral inner interlayer edge length $\langle(O\text{-}O)^{lat}\rangle_{in}$ $(=1/6\cdot[4\cdot(O1\text{-}O2)^{lat}_{in} + 2\cdot(O2\text{-}O2)^{lat}_{in}])$. The solid lines that are shown represent a 1:1 correspondence between the *x* and *y* axes. A histogram displaying the distribution of the normalized size difference between the two inner basal distances, (100 %) $[(O1\text{-}O2)^{lat}_{in} - (O2\text{-}O2)^{lat}_{in}] / \langle(O\text{-}O)^{lat}\rangle_{in}$, is also shown.

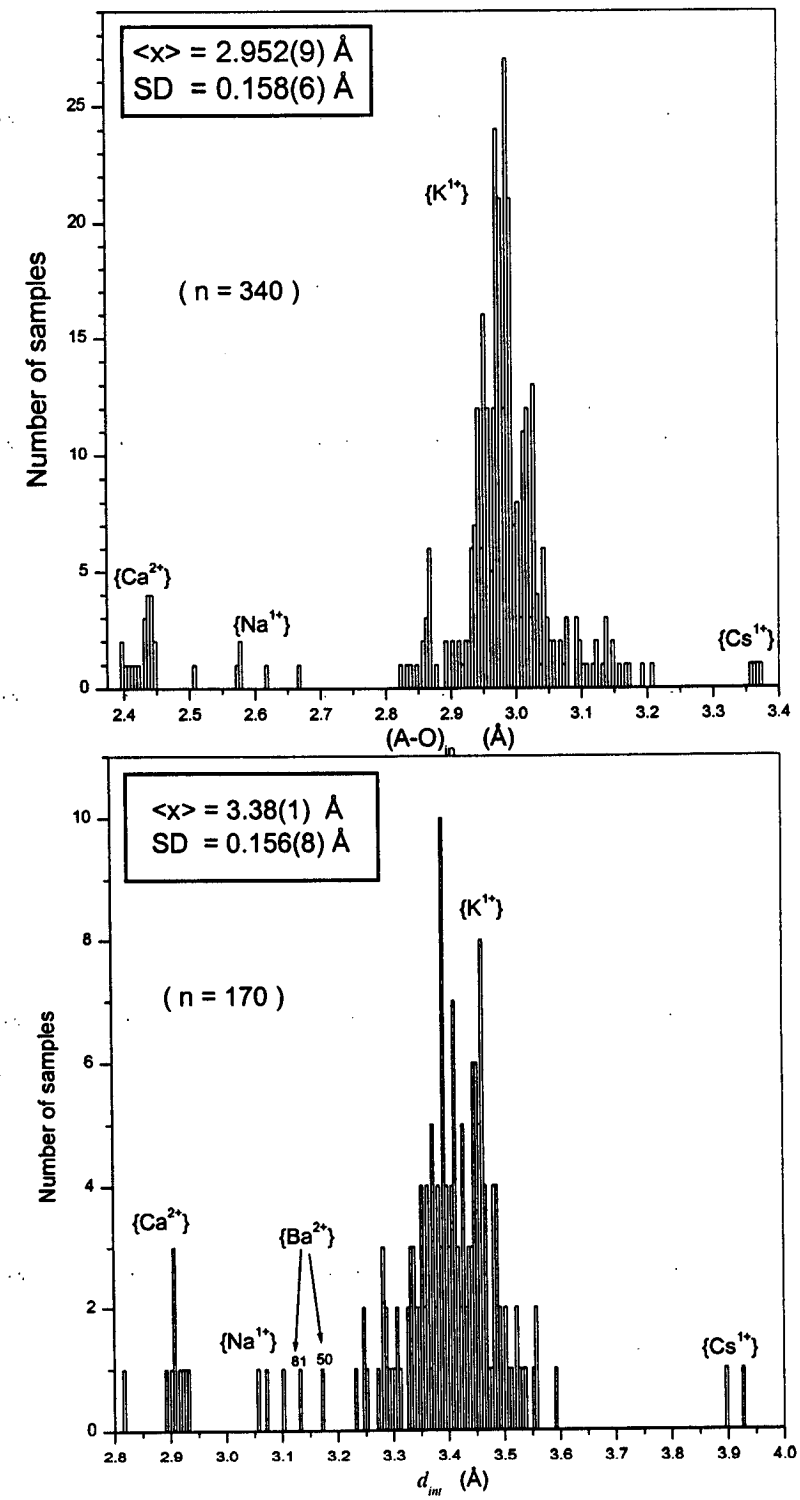

Figure 6.52. Histograms showing the distributions of inner *A-O* bond lengths (top) and interlayer distances d_{int} (bottom) observed in 1*M* structures. The two different inner interlayer bond lengths $(A\text{-}O1)_{in}$ and $(A\text{-}O2)_{in}$ are included in a single distribution.

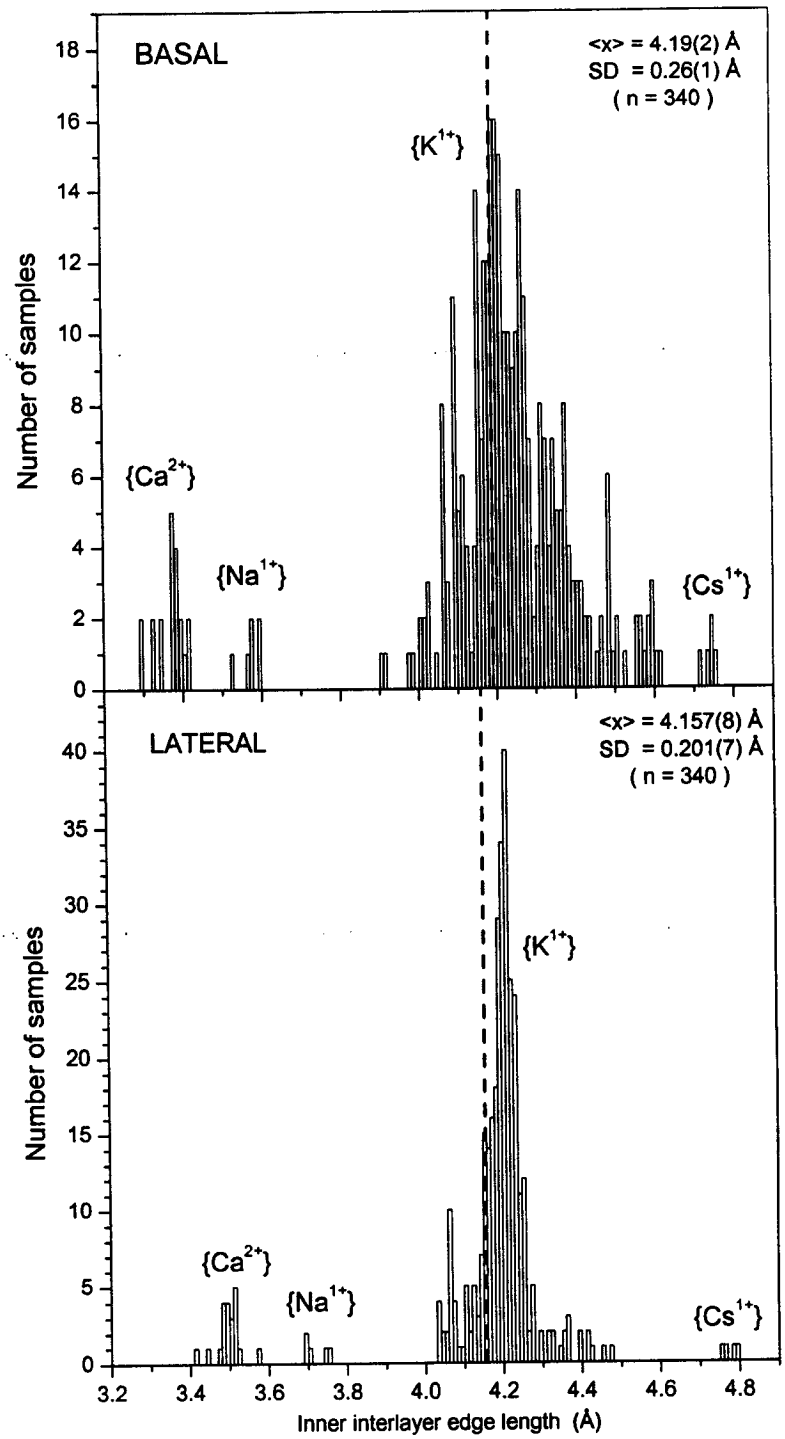

Figure 6.53. Histograms showing the distributions of basal (top) and lateral (bottom) inner interlayer edge lengths observed in 1*M* structures. The two different edge length values of a given type are included in a single distribution for each type. The dashed-lines indicate the average edge length values <x> of each distribution.

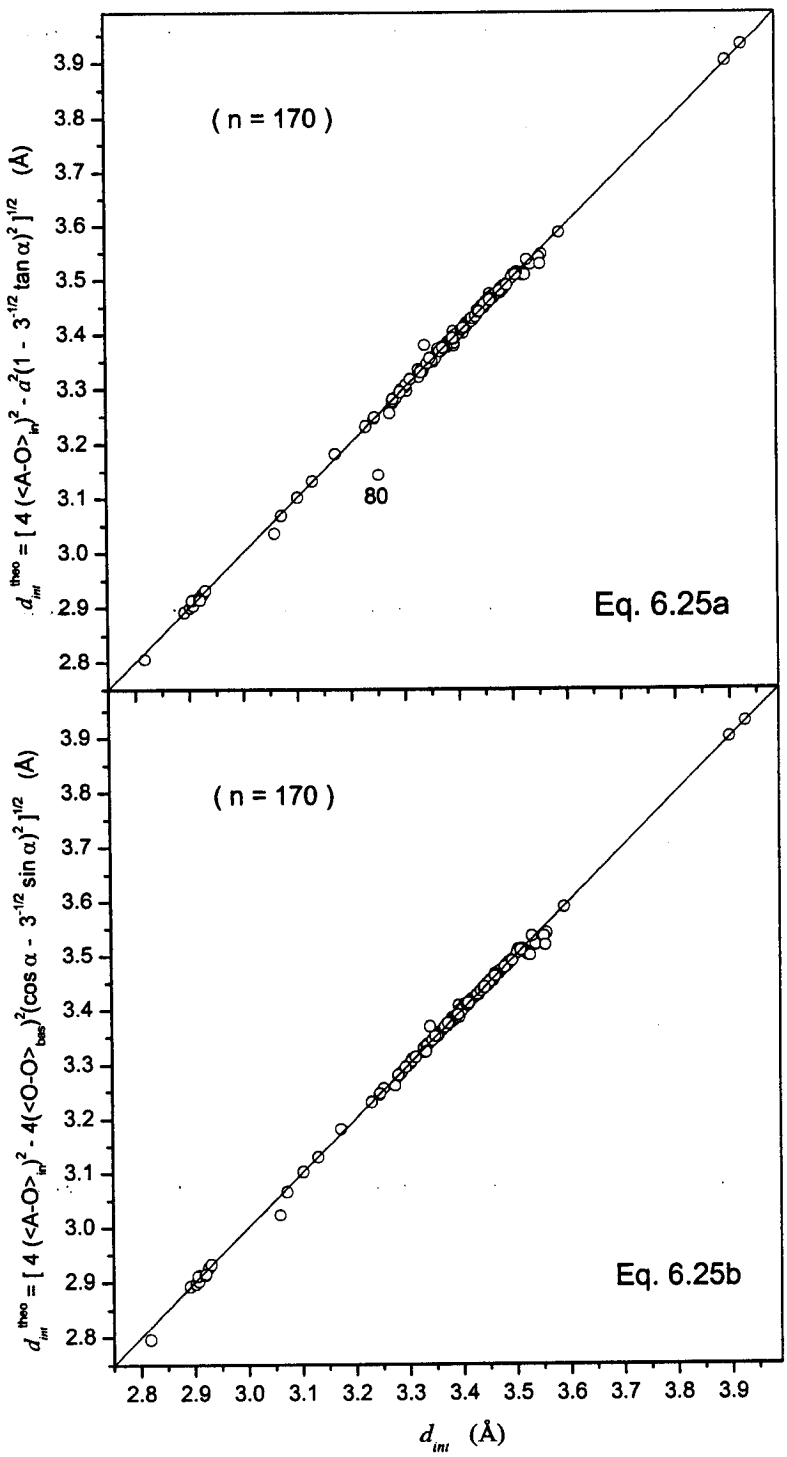

Figure 6.54. Comparison of observed interlayer distances d_{int} (x-axis) to simple geometrical predictions made from Eq. 6.25 (Subsection 6.2.6). The solid lines indicate a 1:1 correspondence between the x and y axes. See text for a detailed description of the figure.

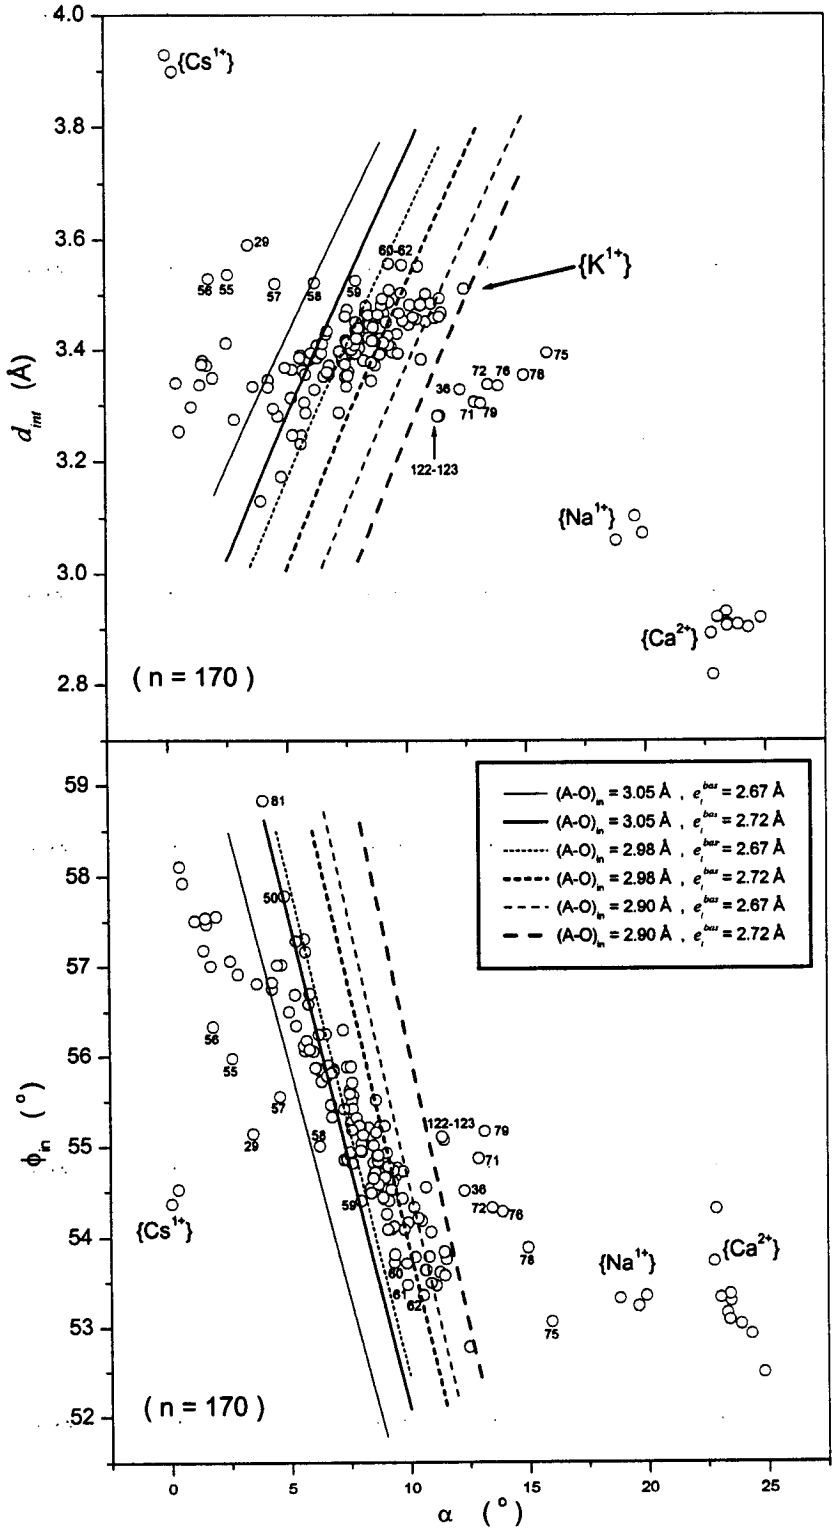

Figure 6.55. Plots of interlayer distance d_{int} and average inner interlayer octahedron flattening angle ϕ_{in} as functions of the average tetrahedral rotation angle α. The various lines (solid, dashed, or dotted) give predictions made from Eq. 6.25b. See text for a detailed description of the figure.

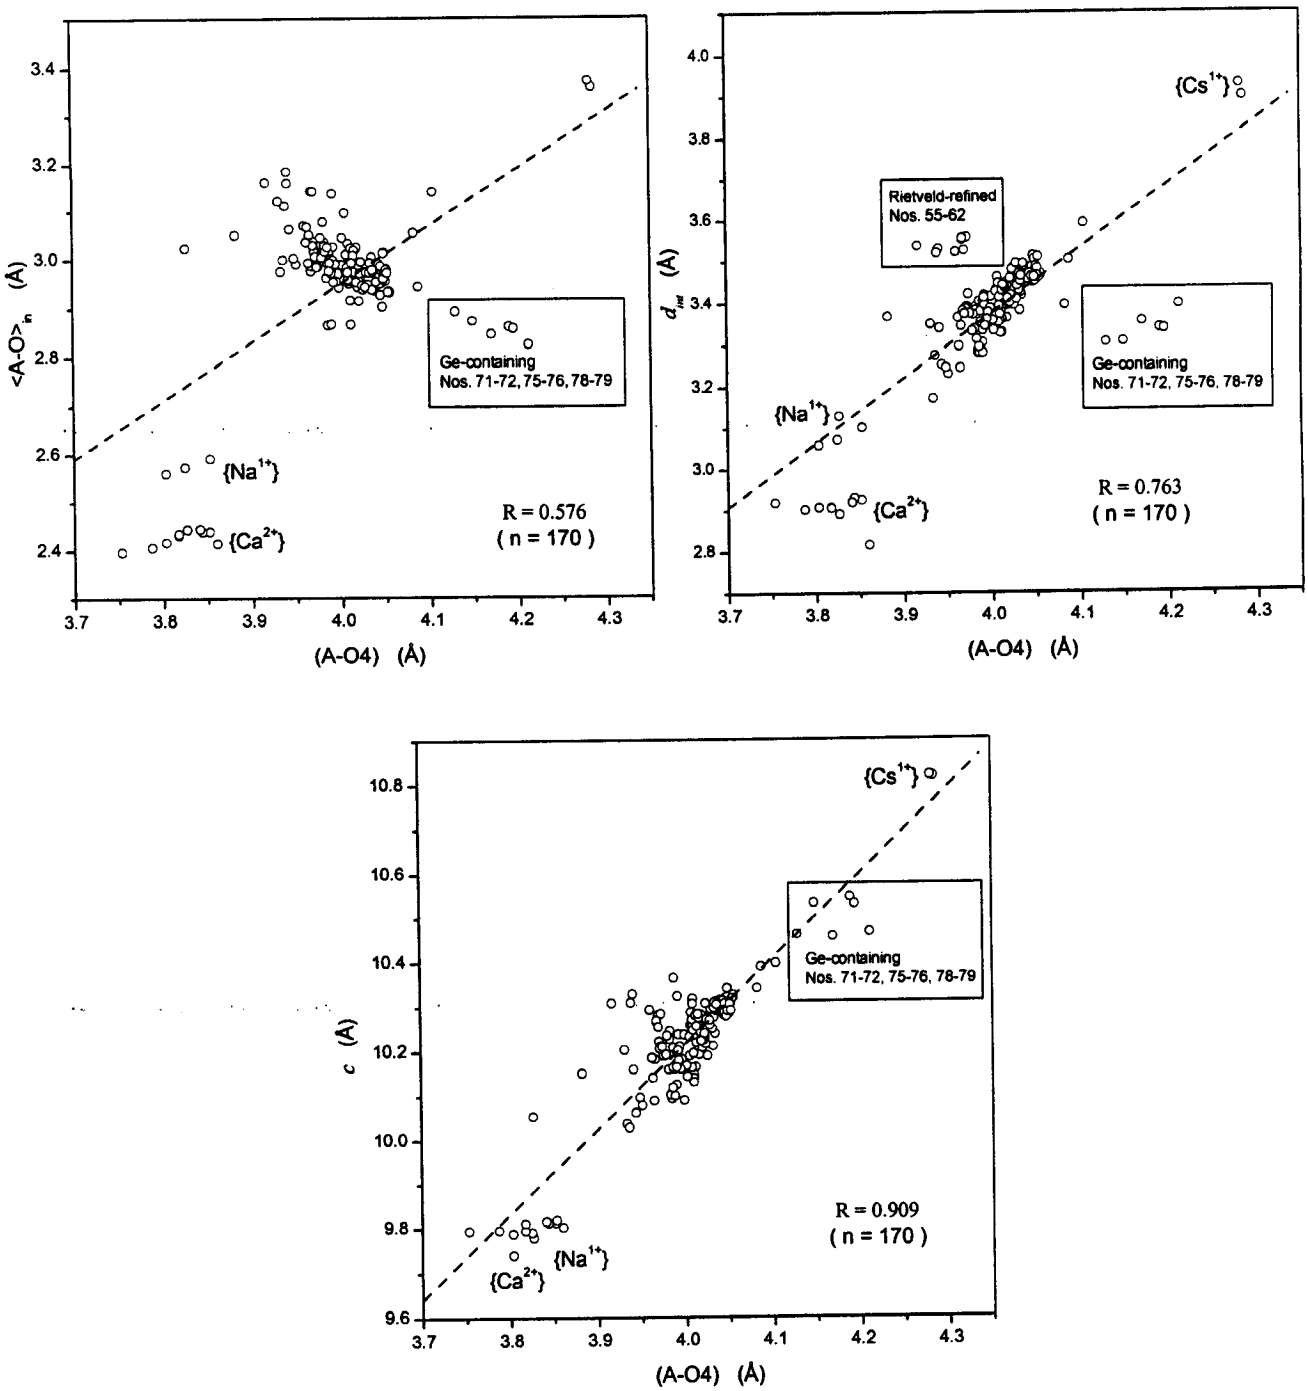

Figure 6.56. Plots of average inner interlayer bond length $\langle A\text{-}O\rangle_{in}$, interlayer distance d_{int}, and lattice parameter c as functions of the (A-O4) distance. The dashed lines that are shown are best straight-line fits through the data. See text for a detailed description of the figure.

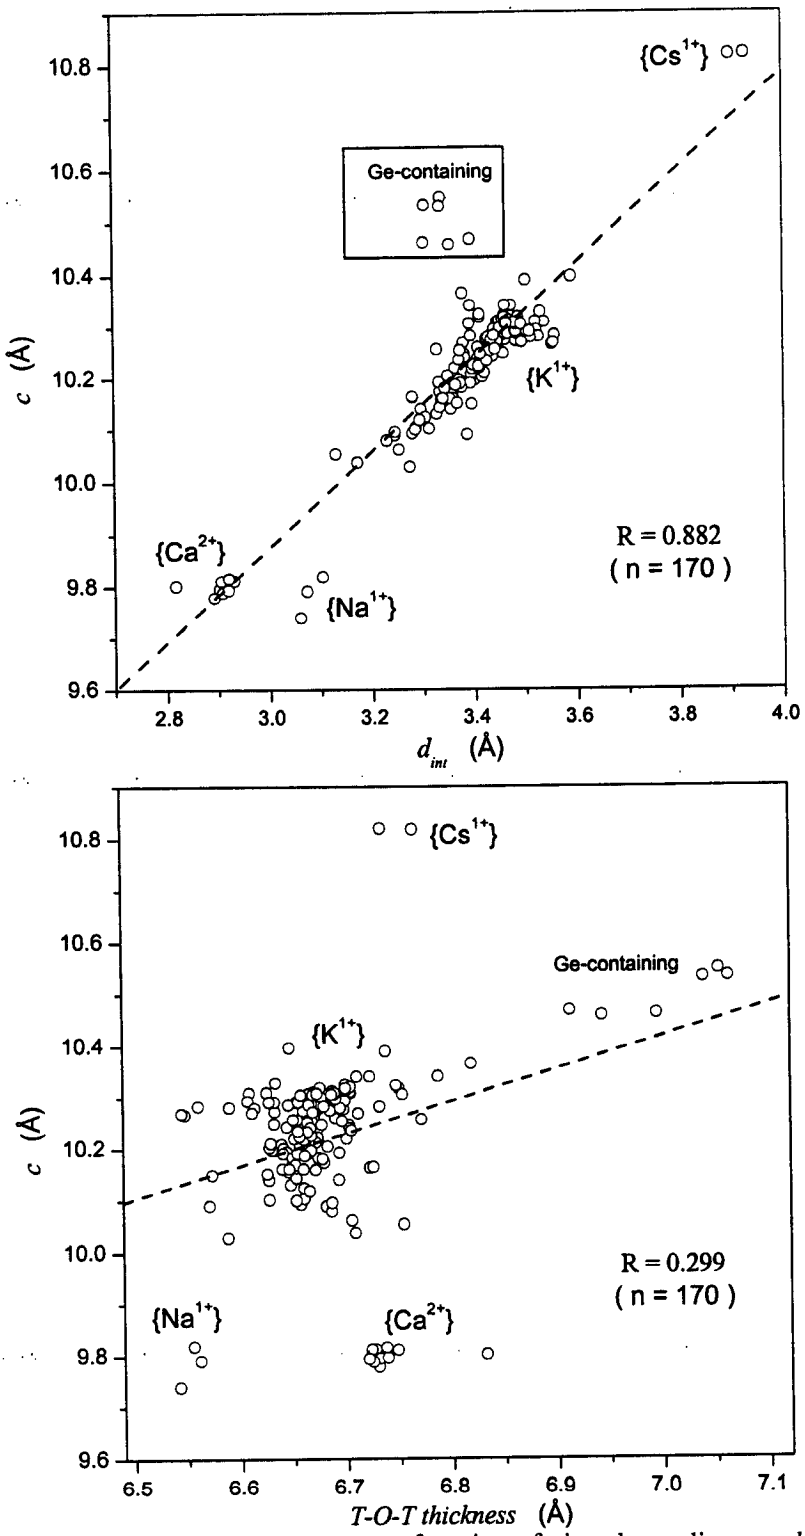

Figure 6.57. Plots of lattice parameter c as a function of: interlayer distance d_{int} (top) ; and overall *T-O-T thickness* (bottom). The dashed lines that are shown are best straight-line fits through the data. See text for a detailed description of the figure.

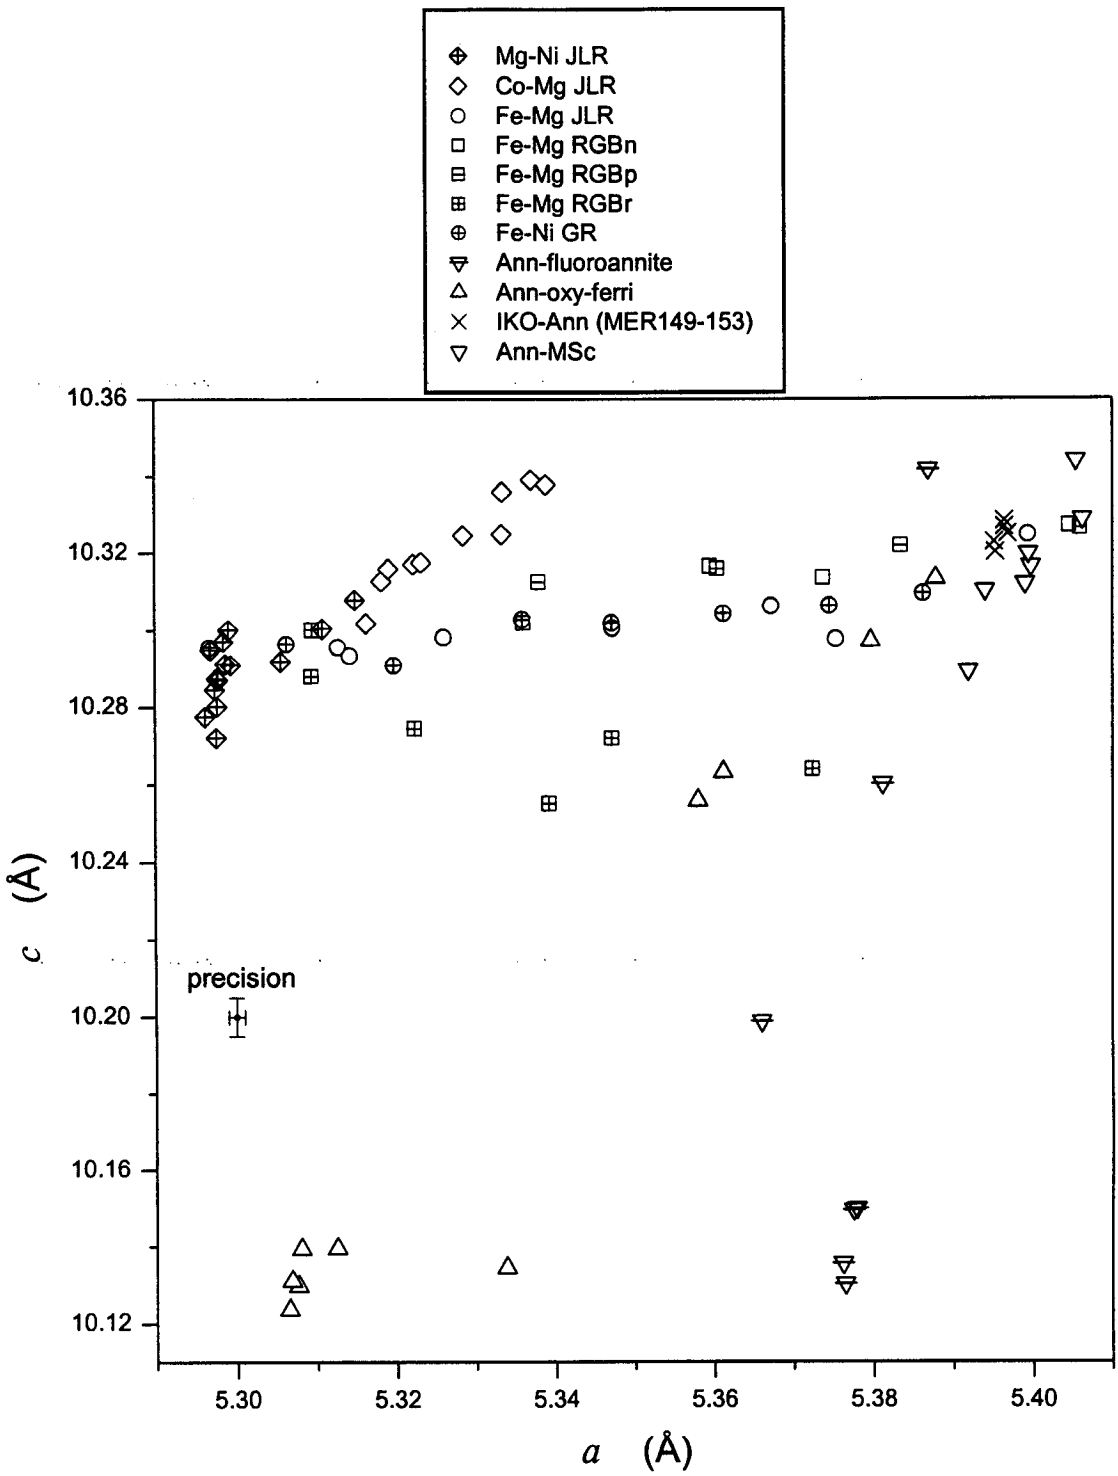

Figure 6.58. *c vs. a* for synthetic samples studied in this thesis. The labelled symbols indicated in the legend refer to the sample solid solutions series described in Table 3.1. The Ann-MSc refers to the synthetic annite samples studied in [Mercier 1996].

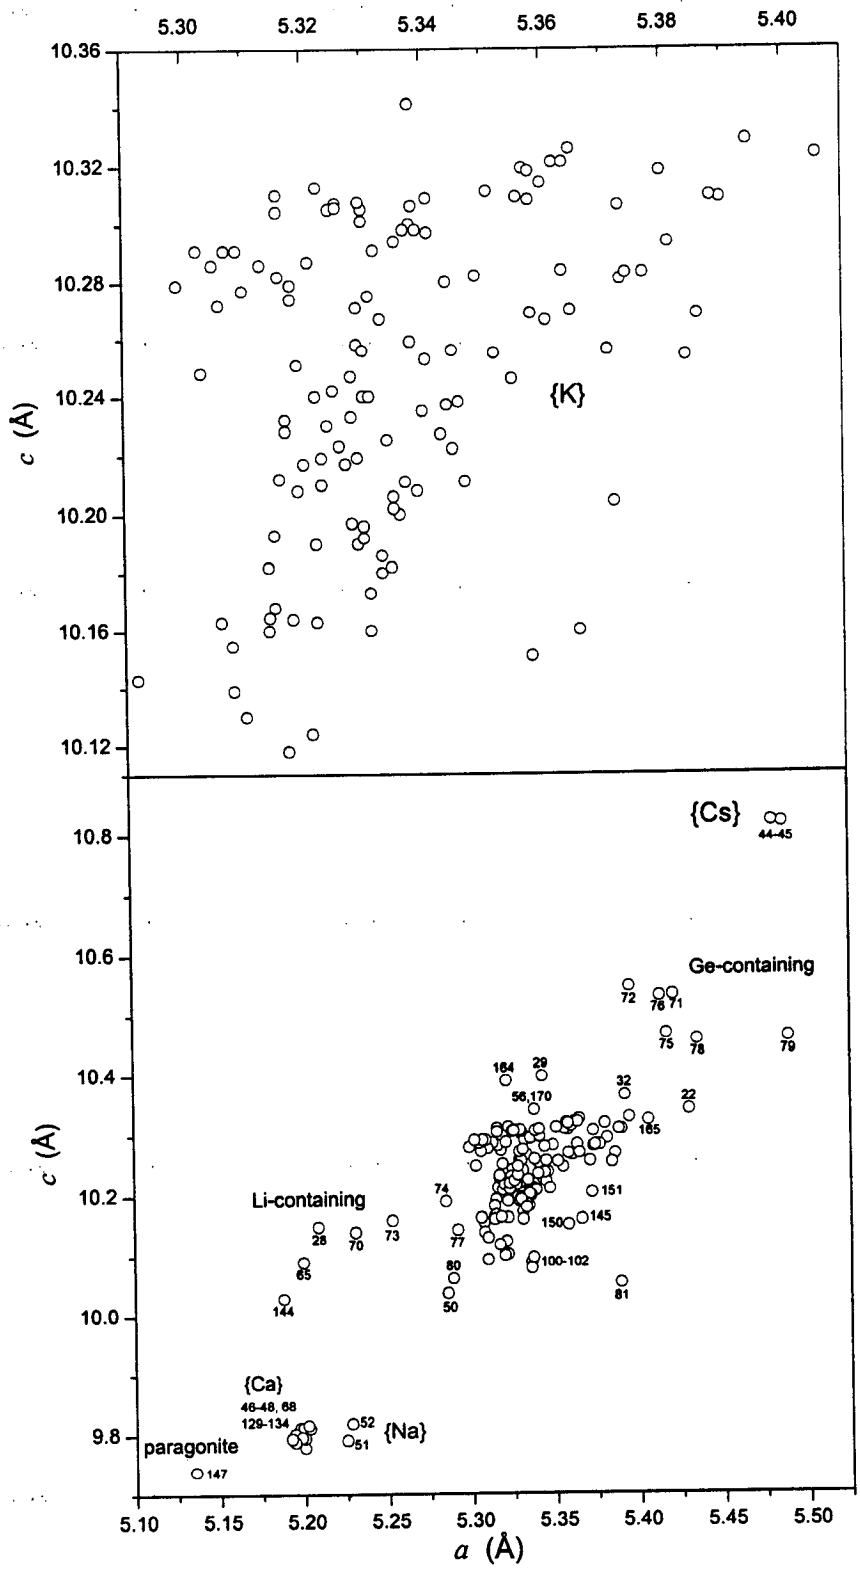

Figure 6.59. *c vs. a* for single-crystal structure refinements of 1*M* structures tabulated in Appendix P. The top graph is a blow-up of a region having the same scale as the plot of *c vs. a* for synthetic samples shown in the previous page.

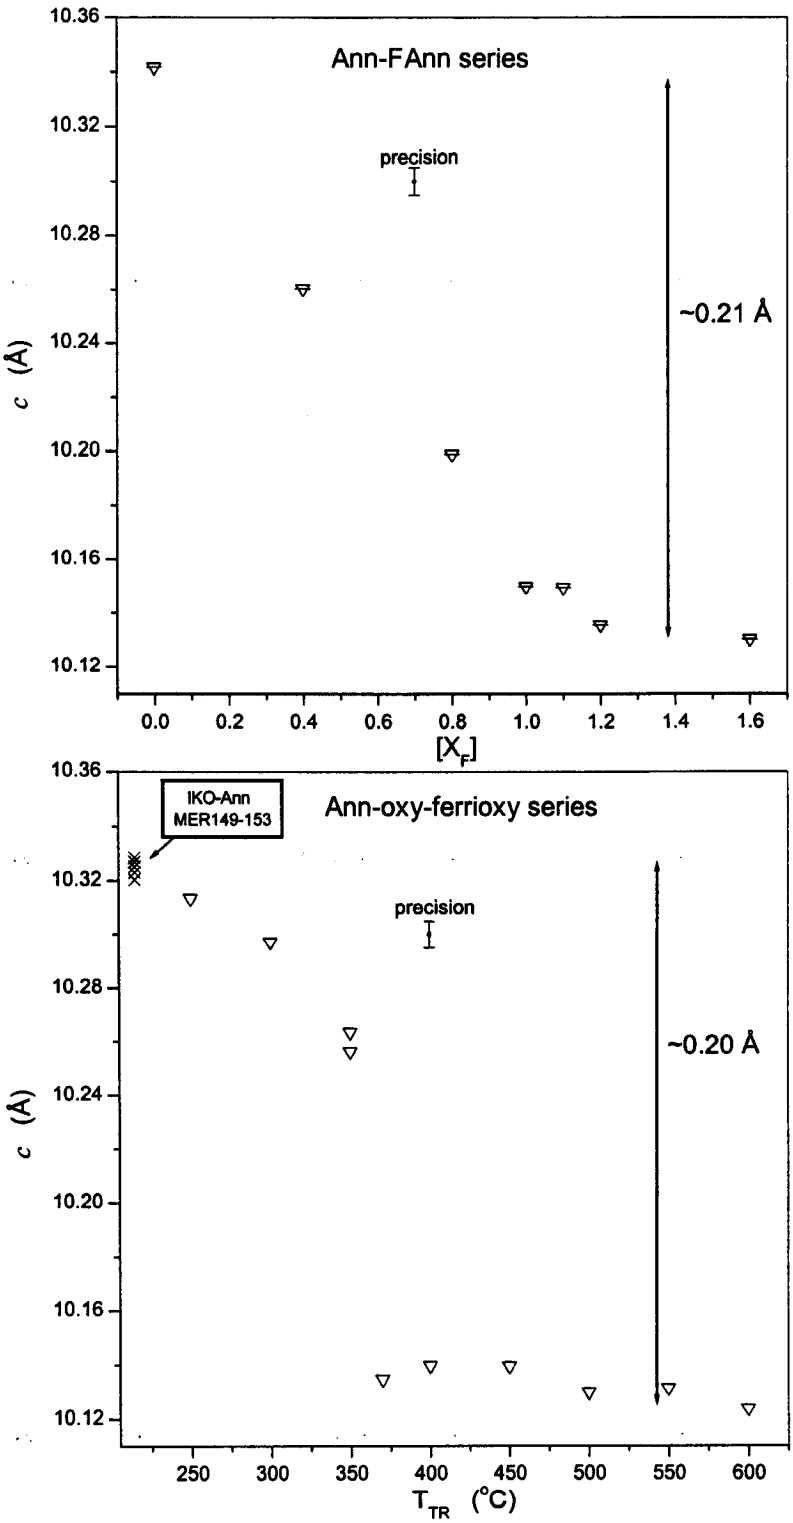

Figure 6.60. Evolutions of *c* for the annite-fluoroannite (top) and the annite-oxyannite-ferrioxyannite (bottom) series as functions of the nominal F content [X_F] and the heat-treatment temperature T_{TR}, respectively. Consult Section 3.2 for details of sample synthesis and heat-treatment conditions (Table 3.1).

6.3.5 Geometric meso-octahedral nature of in-plane intra-layer displacements

In Subsection 6.3.2, it was shown that the normalized squared octahedral size difference $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$ observed in 1*M* structures is a single variable function of the counter-rotation angle of the *M*2 octahedron (Figure 6.32), in accordance with a geometric meso-octahedral sheet model (Subsection 6.2.3). In this subsection, it shall now be established that the in-plane intra-layer displacements between atoms of a given type located above and below the octahedral-cation plane are related to the geometric meso-octahedral character of the octahedral sheets.

Consider the in-plane projection of a geometric meso-octahedral sheet pictured in Figure 6.61, which displays the lateral shift vectors $\vec{\Delta}$ occurring between the positions that *O*3 and *O*4 atoms take when $d_{M1} > d_{M2}$ and the positions that these atoms would adopt in a geometric homo-octahedral sheet having the same *a* and *b* lattice parameters. As a result of the lateral shifts introduced by the $\vec{\Delta}$ vectors, the projections in the *a*-*b* plane of the O3 and O4 atoms lying above and below the octahedral-cation plane are no longer superimposed one over the other, as in a geometric homo-octahedral sheet.

Let us now determine the magnitude of the lateral shift vectors $\vec{\Delta}$. Using a sine law, one can show that the small shaded triangle illustrated in Figure 6.61 gives rise to the following relation:

$$\frac{\left\|\vec{\Delta}\right\|}{\sin \delta_{M2}} = \frac{d_{M2} \sin \psi_{M2}}{\sin 60^\circ} \quad . \tag{6.46}$$

In the above expression, the symbols have the following meanings: i) $\left\|\vec{\Delta}\right\|$ is the norm of a single $\vec{\Delta}$ vector; ii) δ_{M2} is the counter-rotation angle of an *M*2 octahedron; iii) d_{M2} is the *M*-*O* bond length of an *M*2 octahedron; and iv) ψ_{M2} is the flattening angle of an *M*2 octahedron.

In a manner similar as above, another relationship involving $\left\|\vec{\Delta}\right\|$, δ_{M2}, d_{M2}, and ψ_{M2} can be obtained from the sides of the triangle delimited by thick solid lines drawn in Figure 6.61:

$$\frac{a/3 + \left\|\vec{\Delta}\right\|}{\sin\left(30^\circ + \delta_{M2}\right)} = \frac{d_{M2} \sin \psi_{M2}}{\sin 30^\circ} \quad . \tag{6.47}$$

This triangle (i.e., the one delimited by thick solid lines) was also considered in the derivations of Eqs. 6.34 and 6.35 (Subsection 6.3.2).

Next, by equating Eqs. 6.46 and 6.47, one obtains an expression for the magnitude of the lateral shift vectors $\vec{\Delta}$ in terms of the lattice parameter a and the counter-rotation angle δ_{M2}:

$$\frac{\|\vec{\Delta}\|}{a} = \frac{1}{3}\left[\frac{\sin\delta_{M2}}{\sqrt{3}\sin\left(30^\circ+\delta_{M2}\right)-\sin\delta_{M2}}\right] . \tag{6.48}$$

Recalling Eq. 6.35, one has

$$\frac{d_{M1}\sin\psi_{M1}-d_{M2}\sin\psi_{M2}}{a} = \frac{1}{\sqrt{3}}\left[\frac{\sin\left(30^\circ+\delta_{M2}\right)-\sin 30^\circ}{\sin\left(120^\circ+\delta_{M2}\right)}\right] . \tag{6.35}$$

We hence have a set of parametric equations that depend on the counter-rotation angle δ_{M2}. As a function of δ_{M2}, Eq. 6.48 provides a means to obtain theoretical values of in-plane intra-layer displacements between atoms of a given type located above and below the octahedral-cation plane, whereas Eq. 6.35 gives the in-plane size difference of $M1$ and $M2$ octahedrons.

In order to test the above ideas, however, one must first define appropriate in-plane intra-layer displacements for each atom-type of the 1M structure. This was accomplished by taking in-plane distances along a[1] between the projections of various geometric entities on the a axis: i) the distance ID_{xy}^{O3} between the (001) projections of the geometric centres of upper and lower hexagons formed by O3 atoms (Figure 6.61); ii) the distance ID_{xy}^{O4} between the (001) projections of an upper and a lower O4 atoms (Figure 6.61); iii) the distance ID_{xy}^{T} between the (001) projections of the geometric centres of upper and lower hexagons formed by T atoms (Figure 6.62a); iv) the distance $ID_{xy}^{O1\text{-}O2}$ between the (001) projections of the geometric centres of an upper and a lower hexagons formed by basal O1 and O2 oxygen atoms (Figure 6.62b); and v) the distance ID_{xy}^{A} between the projections of two interlayer A cations, one located above the octahedral-cation plane and the other below (Figure 6.62c).

In terms of the fractional coordinates and lattice parameters tabulated for 1M structures in

[1]In the 1M structure, in-plane intra-layer stagger between atoms of a given type located above and below the octahedral-cation plane only occur along the a-axis direction.

Appendix P, one can show that the in-plane intra-layer displacements ID_{xy}^{O3}, ID_{xy}^{O4}, ID_{xy}^{T}, $ID_{xy}^{O1\text{-}O2}$, and ID_{xy}^{A} specified above (Figures 6.61 and 6.62) can be expressed as follows:

(6.49a) $$ID_{xy}^{O3}/a = 2\left[O3x - O3z\,(c/a)\cos\beta^*\right]$$

(6.49b) $$ID_{xy}^{O4}/a = 2\left[O4x + (1/2 - O4z)(c/a)\cos\beta^*\right]$$

(6.49c) $$ID_{xy}^{T}/a = 2\left[Tx - Tz(c/a)\cos\beta^*\right]$$

(6.49d) $$ID_{xy}^{O1\text{-}O2}/a = 1/6\left[2 - 4\cdot O1x - 8\cdot O2x + 2(c/a)\cos\beta^*(2\cdot O1z + 4\cdot O2z - 3)\right]$$

(6.49e) $$ID_{xy}^{A}/a = (c/a)\cos\beta^*$$

The values given by Eqs. 6.49a-6.49e are referred to as 'normalized' in-plane intra-layer displacements.

Figures 6.63-6.67 show the evolutions of normalized in-plane intra-layer displacements ID_{xy}^{O3}/a, ID_{xy}^{O4}/a, ID_{xy}^{T}/a, $ID_{xy}^{O1\text{-}O2}/a$, and ID_{xy}^{A}/a as functions of the in-plane normalized octahedral size difference $[\langle M1\text{-}O\rangle \sin\psi_{M1} - \langle M2\text{-}O\rangle \sin\psi_{M2}]/a$, respectively. These figures allow direct comparisons with the predictions made from Eqs. 6.35 and 6.48.

The solid-line predictions that are shown in Figures 6.63-6.67 stem from the following considerations. In a geometric meso-octahedral sheet, it can be seen in Figure 6.61 that when $d_{M1} > d_{M2}$, then $ID_{xy}^{O3} > a/3$ and $ID_{xy}^{O4} < a/3$; or vice-versa when $d_{M1} < d_{M2}$. By comparison, $ID_{xy}^{O3} = ID_{xy}^{O4} = a/3$ in a geometric homo-octahedral sheet. Given that tetrahedral *T* cations, basal O1 and O2 oxygen atoms, and interlayer *A* cations are all linked to apical O3 oxygen atoms via the tetrahedral sheets in a TOT network, therefore, it is expected that in-plane intra-layer displacements involving *T*, O1, O2, and *A* atoms will behave similarly as those of O3 atoms.

Indeed, this is shown in Figures 6.63-6.67. Except for the few usual outliers, one observes that the data points display a fair agreement with the solid-line predictions made on the basis of Eqs. 6.35 and 6.48, especially for O3 and O4 atoms. This, therefore, represents strong evidence that in-plane intra-layer displacements between atoms of a given type located above and below the octahedral-cation plane are predominantly a direct consequence of the geometric meso-octahedral character of the octahedral sheets.

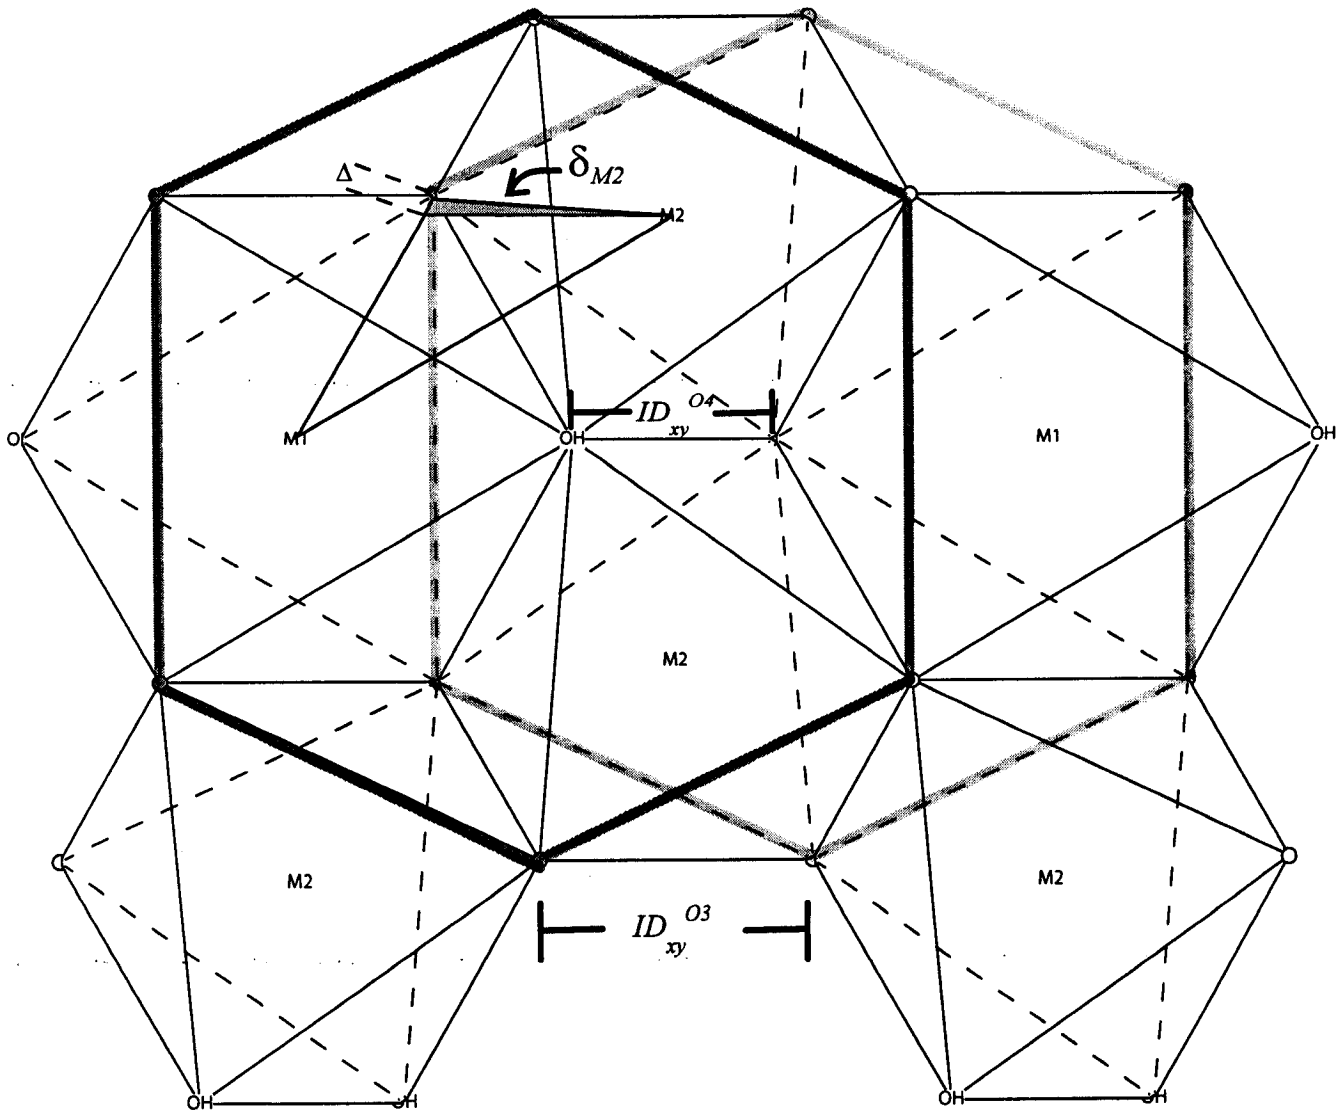

Figure 6.61. Illustration of a geometric meso-octahedral sheet showing the lateral shift vectors $\vec{\Delta}$ that occur when $d_{M1} > d_{M2}$. The in-plane intra-layer displacements ID_{xy}^{O3} and ID_{xy}^{O4} are also shown. See text for a detailed explanation of the use of the two triangles that are drawn.

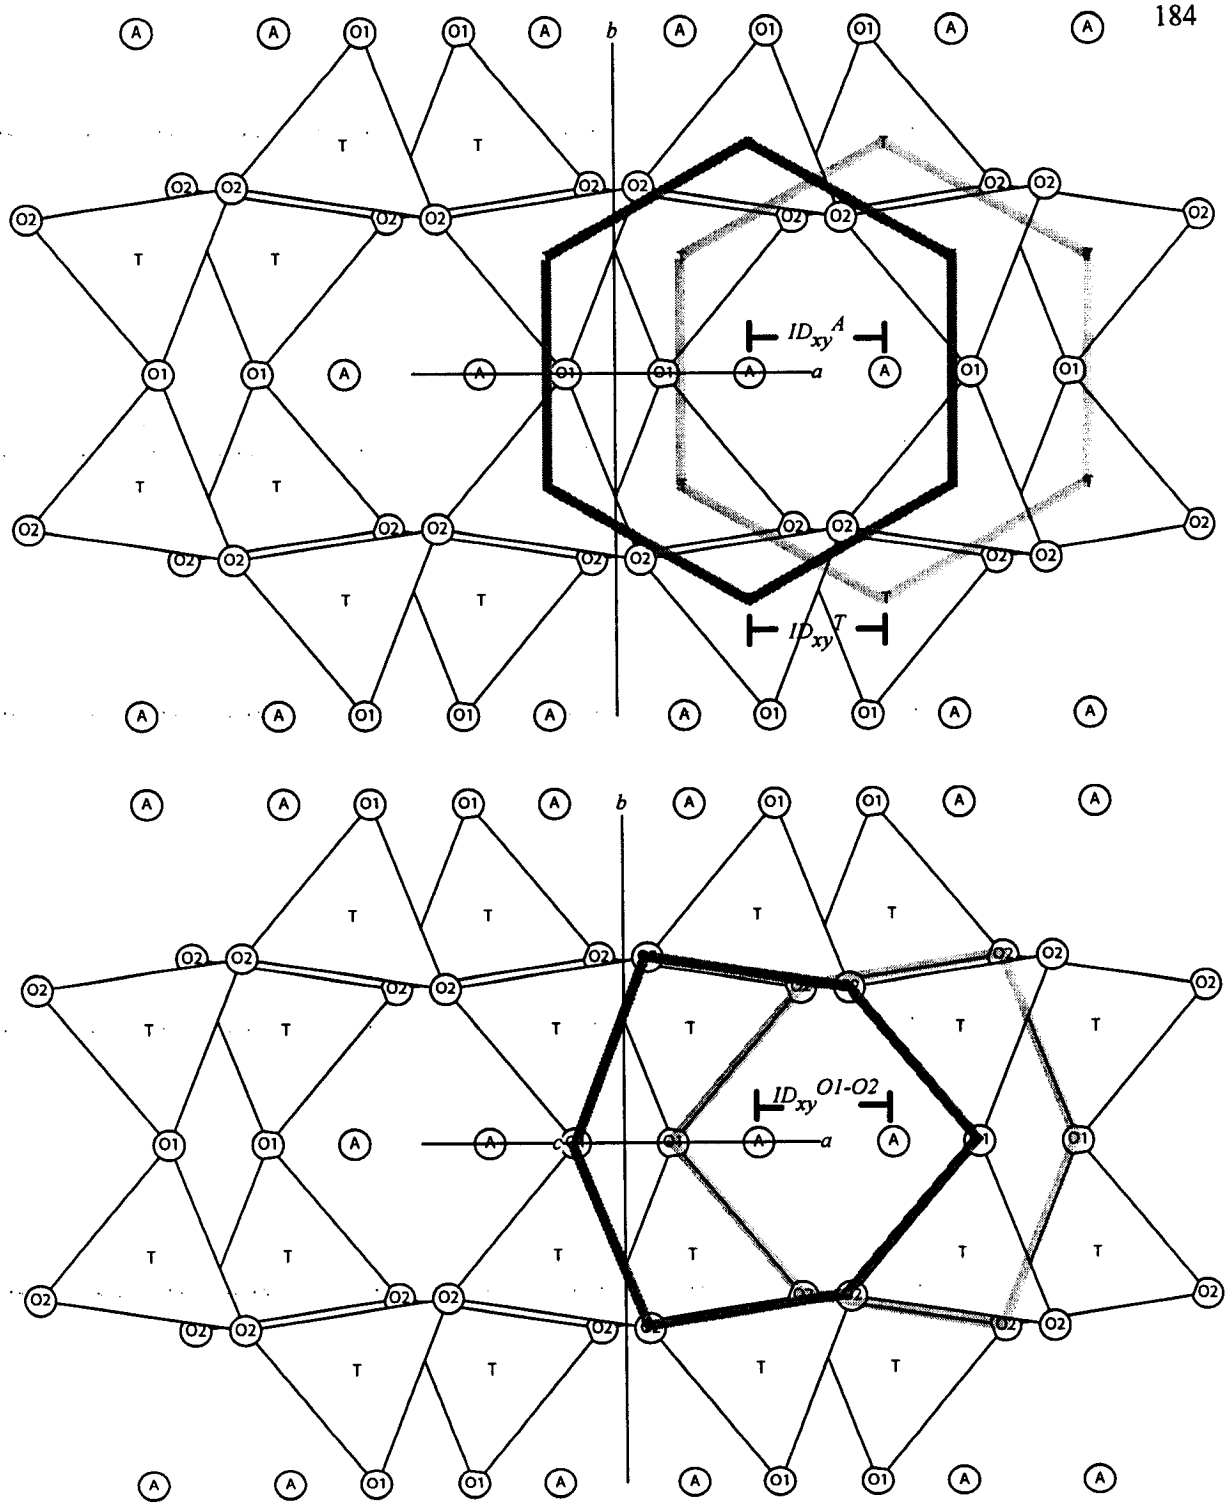

Figure 6.62. Diagrams illustrating in-plane intra-layer displacements that were considered: ID_{xy}^{T}, $ID_{xy}^{O1\text{-}O2}$, and ID_{xy}^{A}.

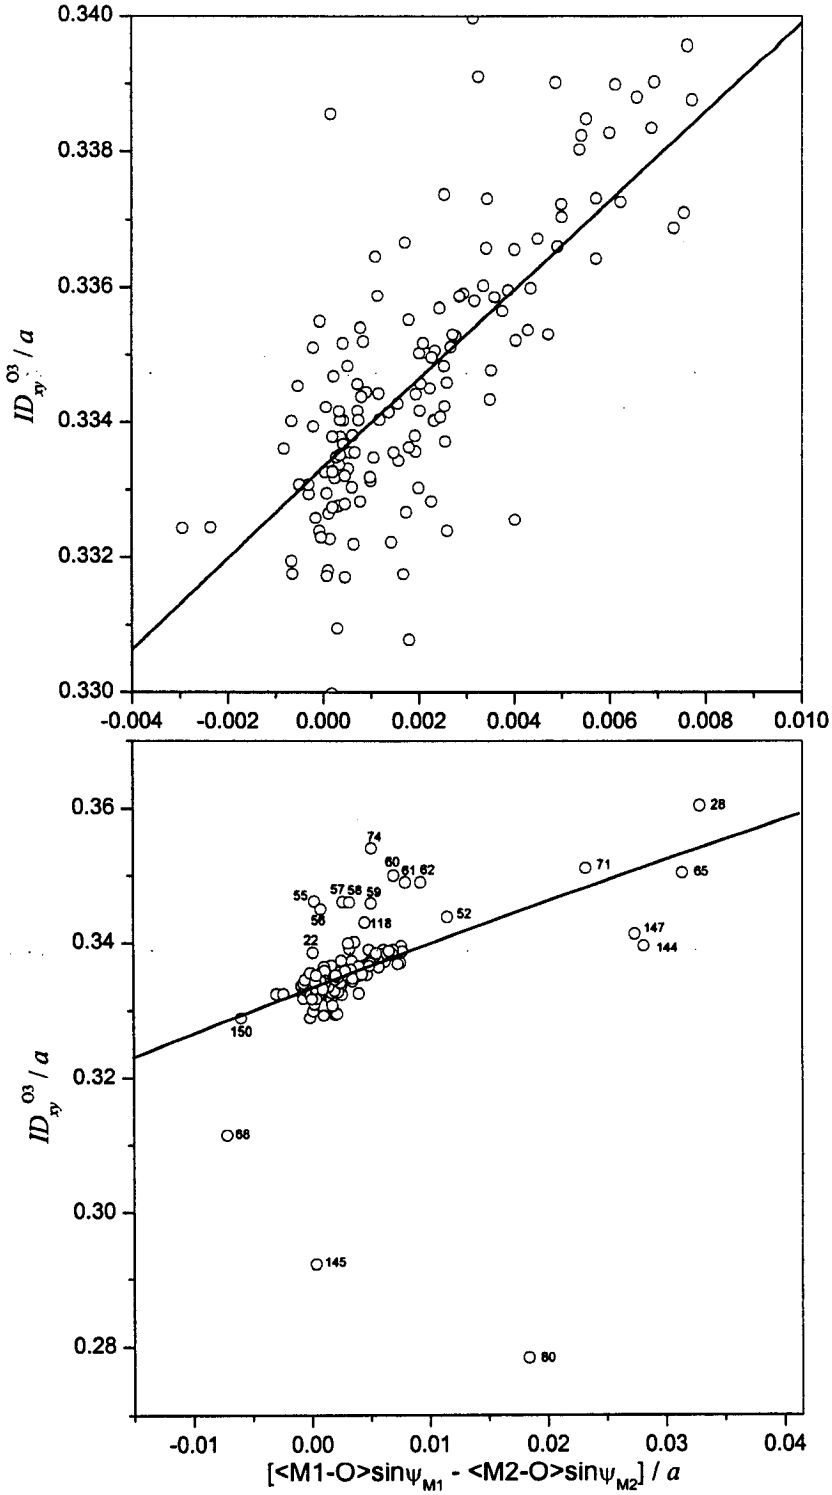

Figure 6.63. Evolution of normalized in-plane intra-layer displacement ID_{xy}^{O3} / a as a function of the normalized size difference $[<M1\text{-}O>\sin\psi_{M1} - <M2\text{-}O>\sin\psi_{M2}]/a$. The solid lines that are shown correspond to predictions made on the basis of Eqs. 6.35 and 6.48.

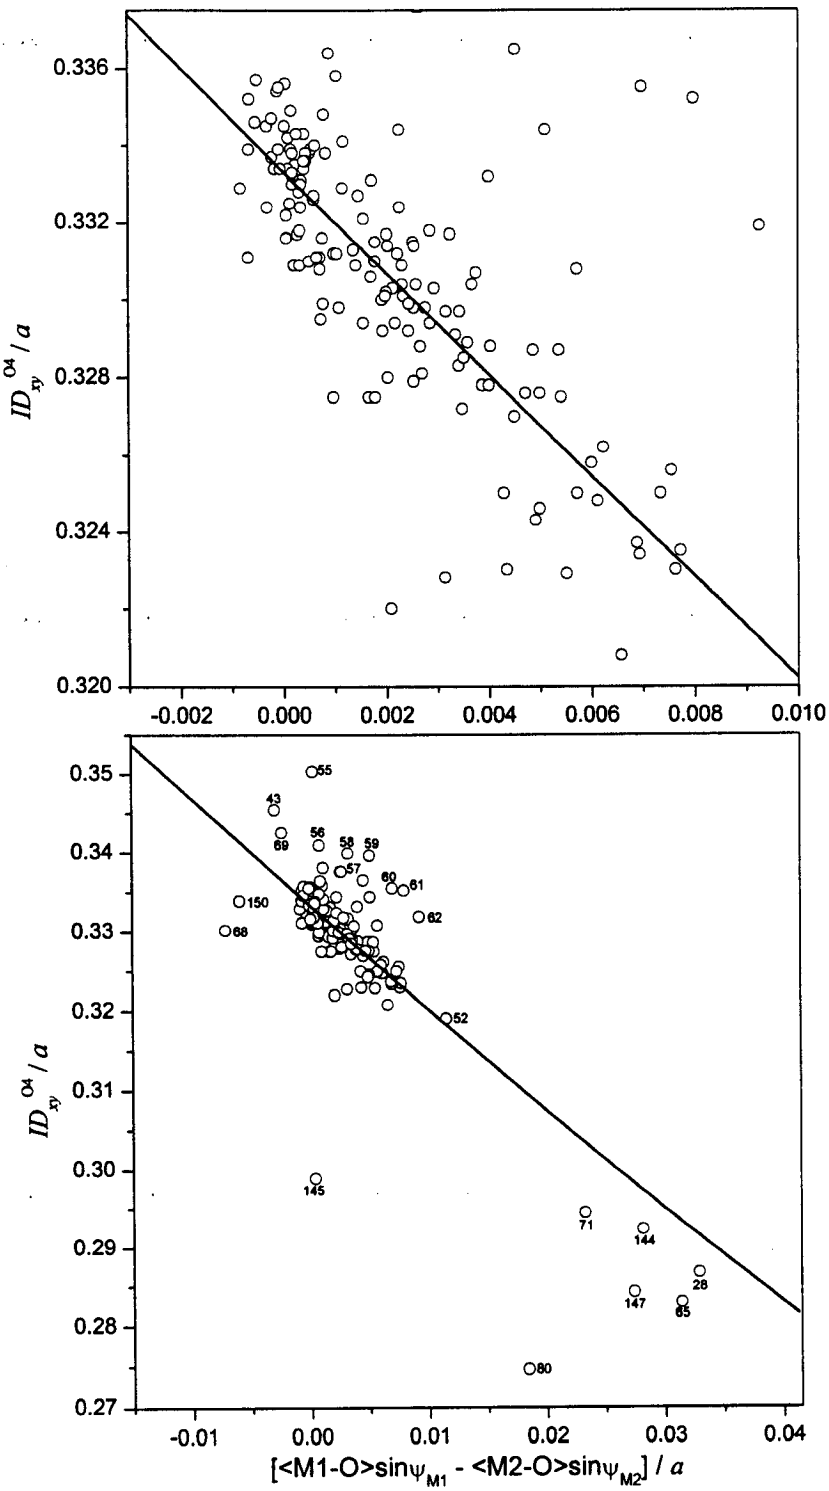

Figure 6.64. Evolution of normalized in-plane intra-layer displacement ID_{xy}^{O4} / a as a function of the normalized size difference [<M1-O>sinψ$_{M1}$ - <M2-O>sinψ$_{M2}$]/a . The solid lines that are shown correspond to predictions made on the basis of Eqs. 6.35 and 6.48.

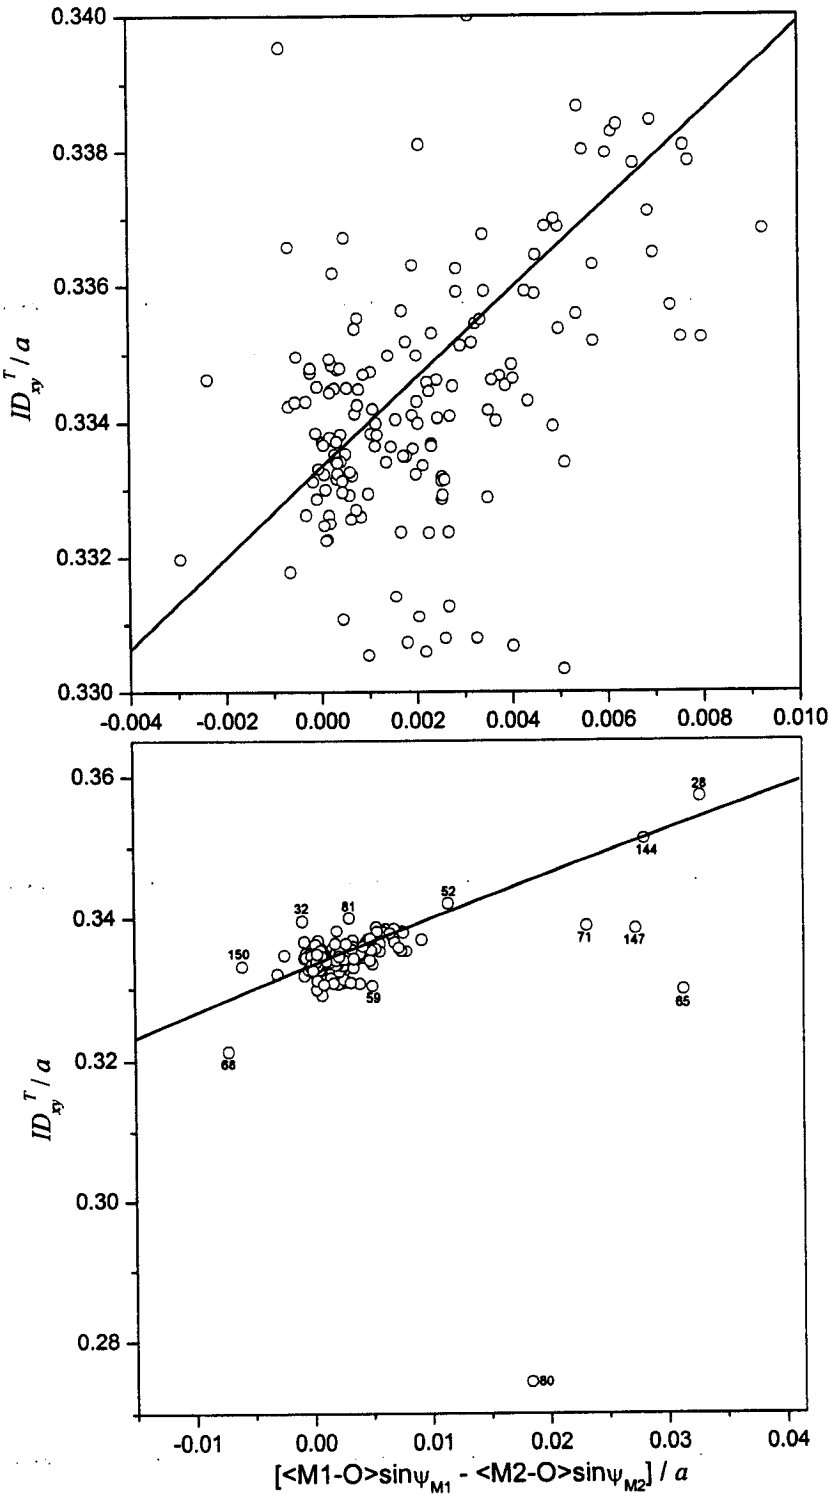

Figure 6.65. Evolution of normalized in-plane intra-layer displacement ID_{xy}^{T} / a as a function of the normalized size difference $[\langle M1\text{-}O\rangle \sin\psi_{M1} - \langle M2\text{-}O\rangle \sin\psi_{M2}]/a$. The solid lines that are shown correspond to predictions made on the basis of Eqs. 6.35 and 6.48.

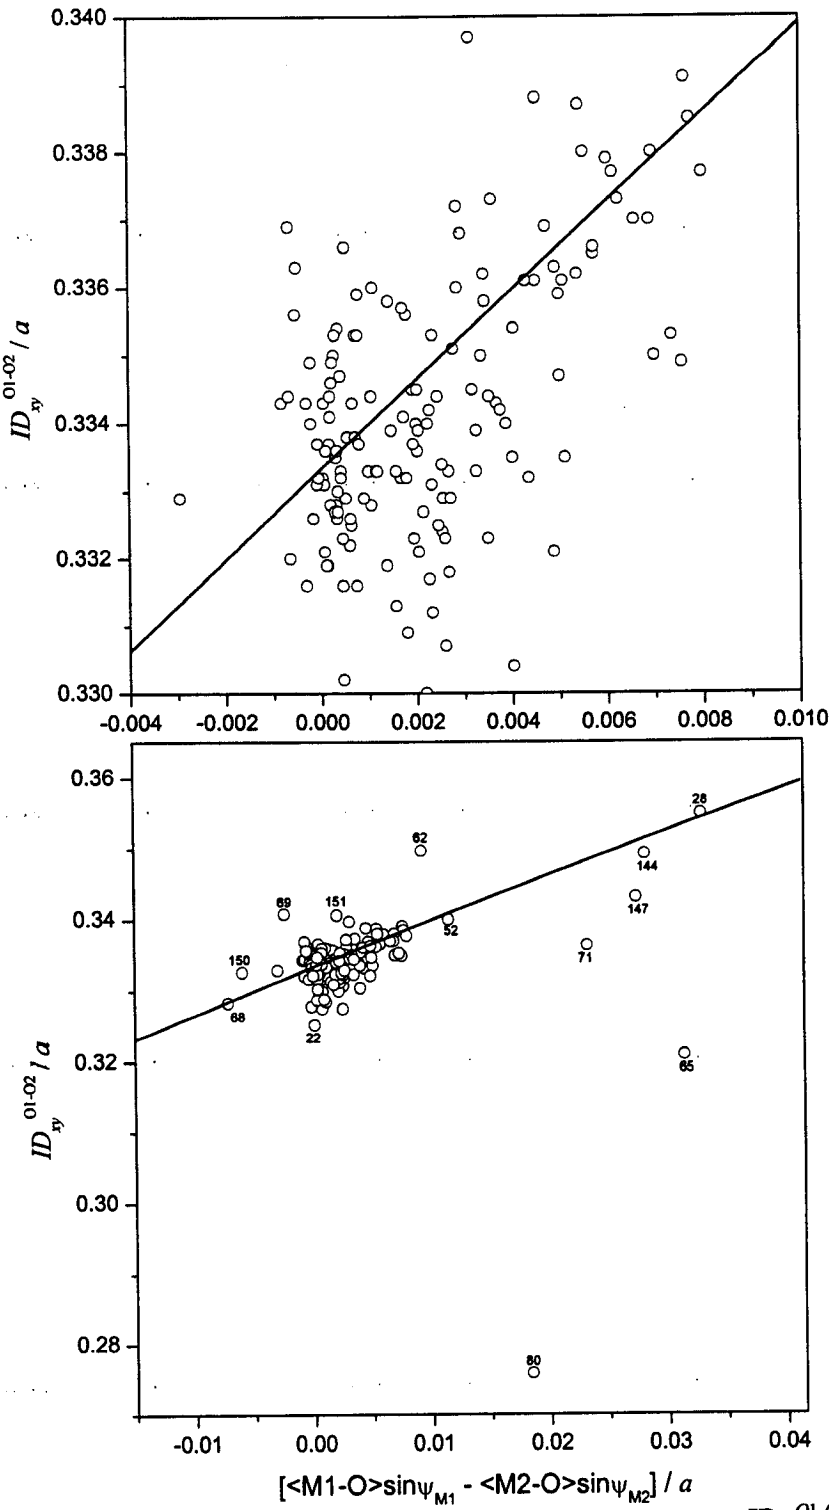

Figure 6.66. Evolution of normalized in-plane intra-layer displacement $ID_{xy}^{O1\text{-}O2} / a$ as a function of the normalized size difference $[<M1\text{-}O>\sin\psi_{M1} - <M2\text{-}O>\sin\psi_{M2}]/a$. The solid lines that are shown correspond to predictions made on the basis of Eqs. 6.35 and 6.48.

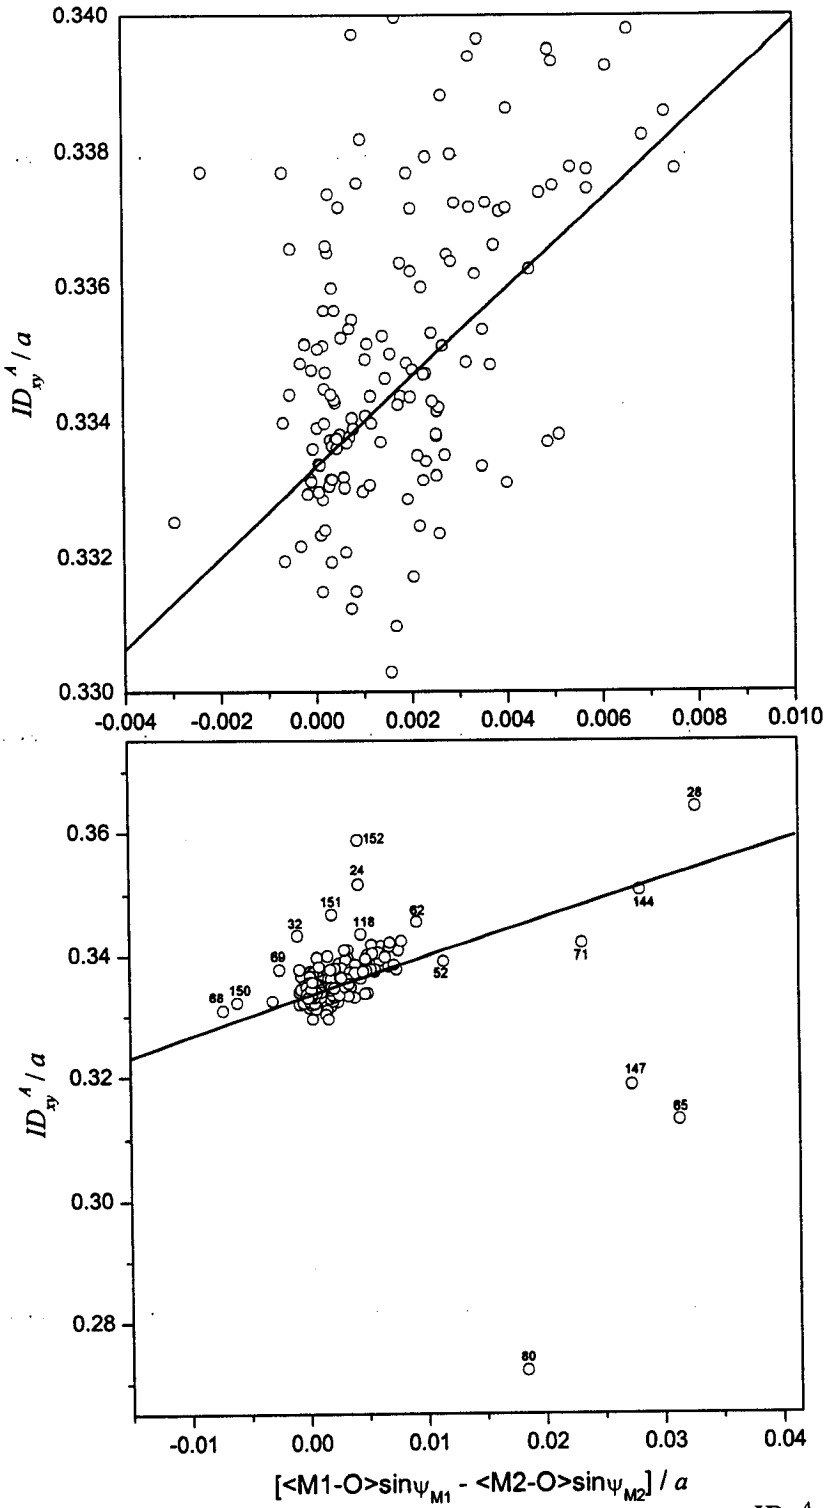

Figure 6.67. Evolution of normalized in-plane intra-layer displacement ID_{xy}^{A} / a as a function of the normalized size difference $[<M1\text{-}O>\sin\psi_{M1} - <M2\text{-}O>\sin\psi_{M2}]/a$. The solid lines that are shown correspond to predictions made on the basis of Eqs. 6.35 and 6.48.

6.3.6 Fundamental difference between synthetic and natural samples

The normalized intra-layer displacement $(c/a)\cos\beta^*$ (where $\beta^* = 180° - \beta$) is referred to as the 'intralayer shift' or 'intralayer stagger' [Brigatti & Guggenheim 2002; Ferraris & Vivaldi 2002]. In a geometric homo-octahedral 2:1 layer silicate, one has $(c/a)\cos\beta^* = 1/3$ (Subsection 6.2.6).

Figure 6.69 displays the distribution of $(c/a)\cos\beta^*$ for the 170 single-crystal structure refinements of 1*M* samples compiled in Appendix P. Clearly, one observes that the distribution is asymmetric and not centred on the dashed line drawn at $(c/a)\cos\beta^* = 1/3$. In light of the previous subsection, therefore, this is attributed to the presence of geometric meso-octahedral sheets in these samples.

It is important to verify the extent to which synthetic and natural samples differ. Figure 6.70 compares the distributions of $(c/a)\cos\beta^*$ for: i) the 128 single-crystal structure refinements of natural 1*M* samples; ii) the 42 single-crystal structure refinements of synthetic 1*M* samples; iii) the 170 single-crystal structure of 1*M* samples, natural and synthetic, on an expanded scale relative to Figure 6.69; and iv) the 75 synthetic samples investigated by powder X-ray diffraction in this thesis. As indicated by the standard deviation (SD) values of the distributions, the synthetic single-crystal distribution is approximately twice thinner than the natural single-crystal one, whereas the distribution of $(c/a)\cos\beta^*$ for the synthetic powder samples of this thesis is one order of magnitude thinner than the two single-crystal distributions.

An alternate way to visualize the above situation is via the plots of $c\cdot\cos\beta^*$ *versus* a presented in Figures 6.71 and 6.72. The solid lines that are shown in each graph of these figures correspond to $(c/a)\cos\beta^* = 1/3$, whereas the error bars reported for the synthetic samples of this thesis incorporate the precision errors of each lattice parameter using the common error propagation method (assuming uncorrelated errors). While in the case of single-crystal structure refinements no clear trend is noticeable, one finds that, within error, the synthetic samples of this thesis agree with the $(c/a)\cos\beta^* = 1/3$ relationship which is predicted for a geometric homo-octahedral 2:1 layer silicate.

From this subsection, therefore, the following conclusions are made: i) strong evidence for a fundamental difference between synthetic and natural samples is found, presumably due to some degree of chemical ordering that is present in natural samples (which causes a geometrical meso-octahedral structure to occur) and not in synthetic ones; and ii) a crystal structure model based on a geometric homo-octahedral network is valid for the synthetic powder samples of this thesis.

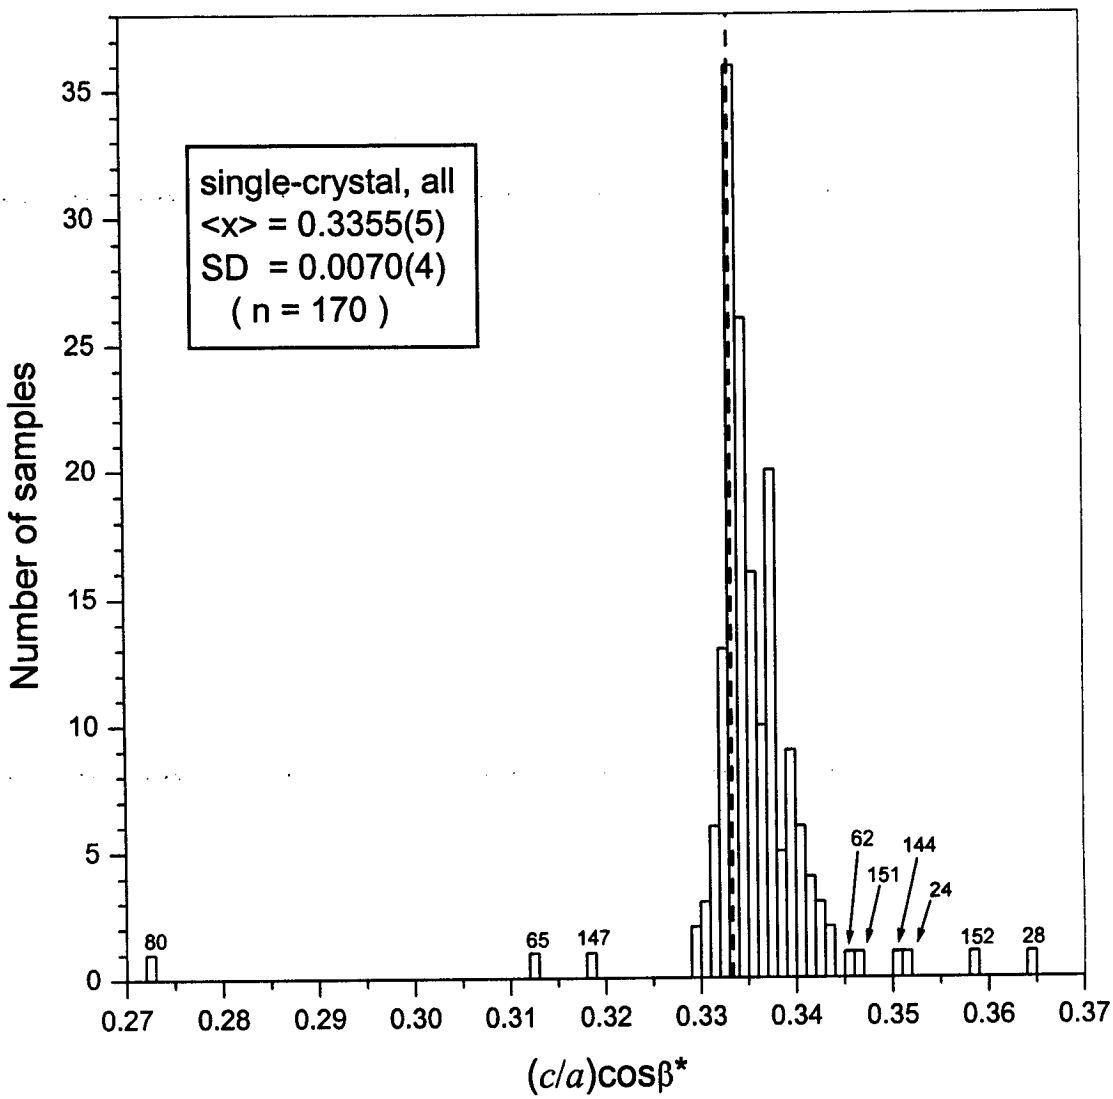

Figure 6.69. Histogram showing the distribution of $(c/a)\cos\beta^*$ for the 170 single-crystal structure refinements of 1*M* samples compiled in Appendix P. The dashed line that is shown corresponds to $(c/a)\cos\beta^* = 1/3$.

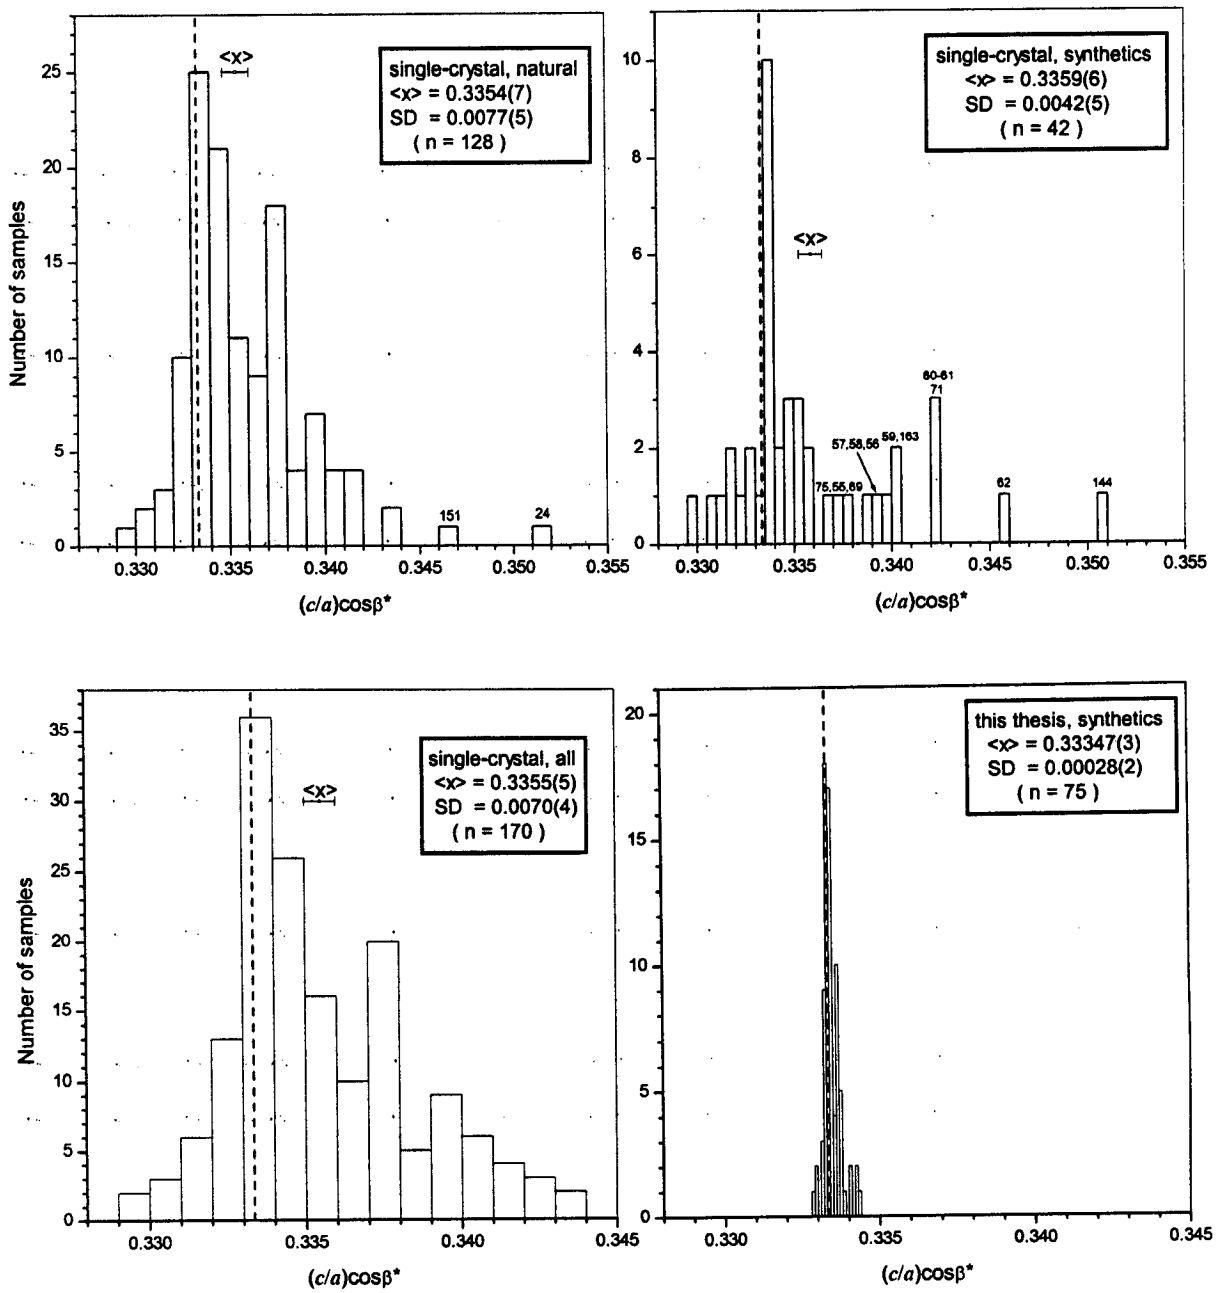

Figure 6.70. Comparison of the distributions of $(c/a)\cos\beta^*$ for: (a) the 128 single-crystal structure refinements of natural 1*M* samples; (b) the 42 single-crystal structure refinements of synthetic 1*M* samples; (c) the 170 single-crystal structures of 1*M* samples, natural and synthetic, on an expanded scale; and (d) the 75 synthetic samples investigated by powder X-ray diffraction in this thesis. The vertical dashed lines correspond to $(c/a)\cos\beta^* = 1/3$.

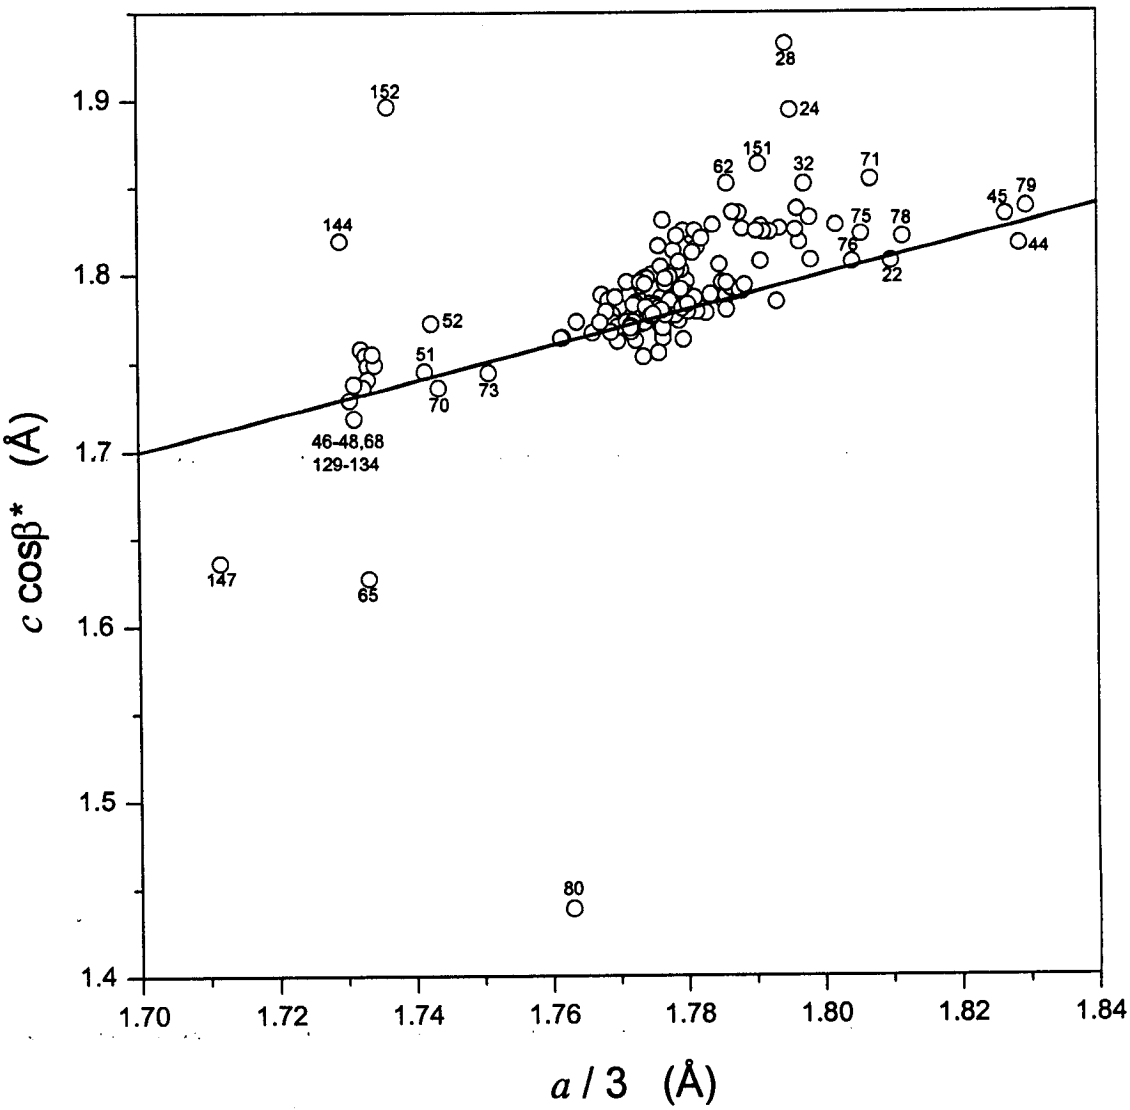

Figure 6.71. Evolution of $c\cos\beta^*$ *versus* a for the 170 single-crystal structure refinements of 1*M* samples compiled in Appendix P. The solid straight line corresponds to $(c/a)\cos\beta^* = 1/3$.

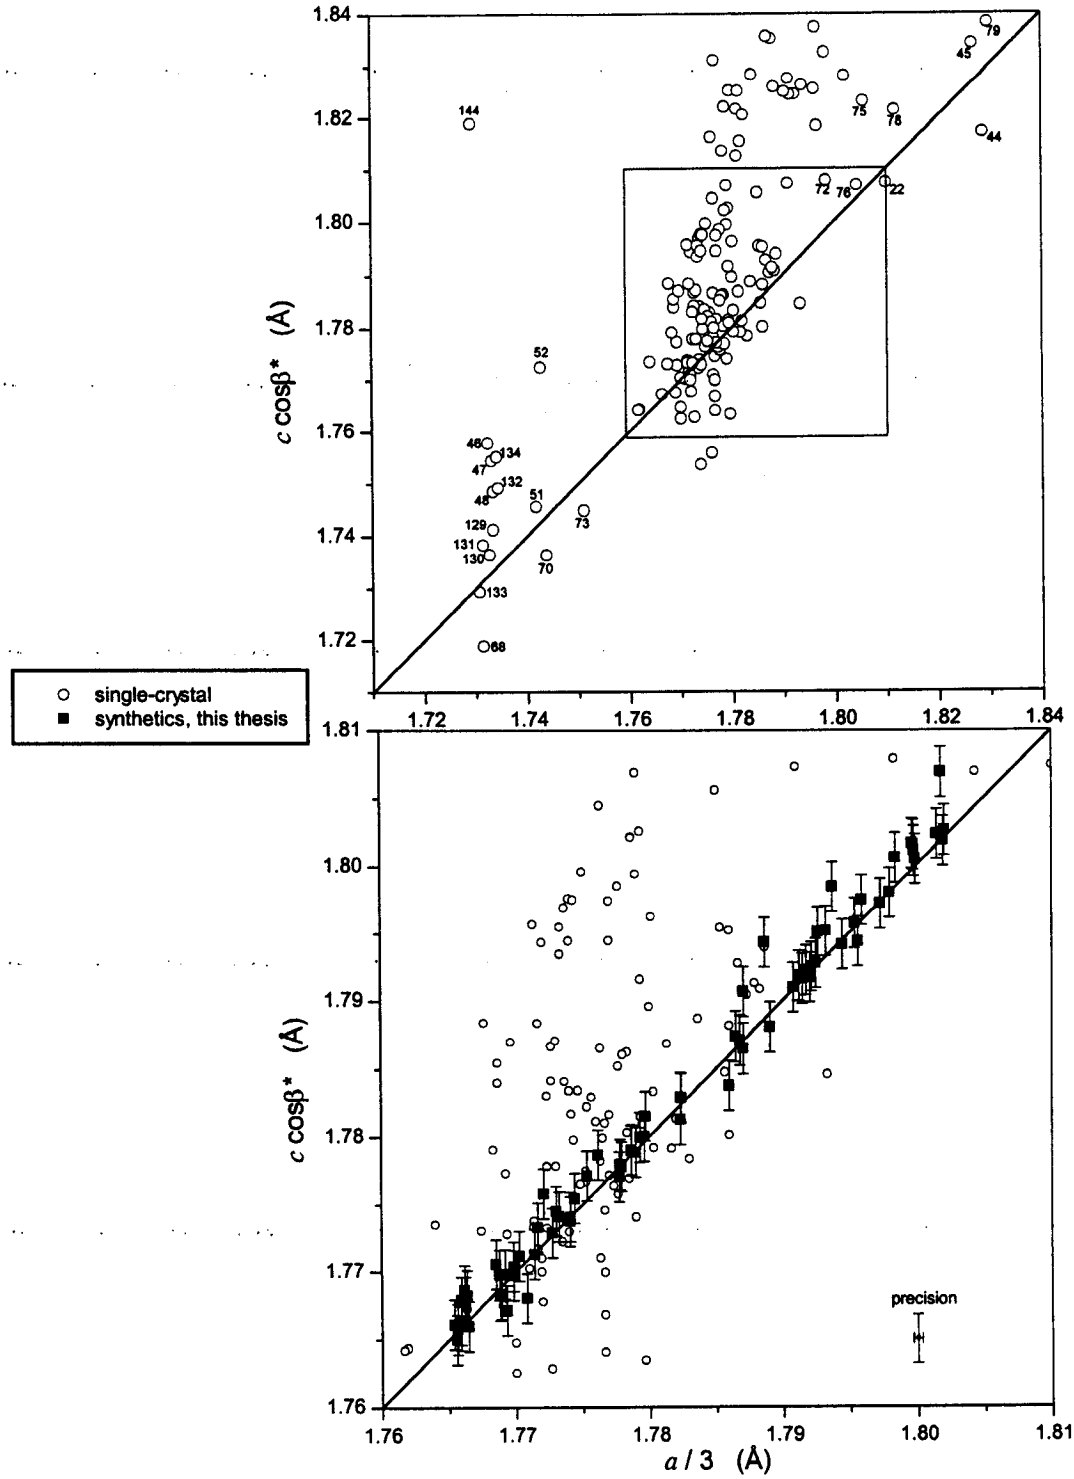

Figure 6.72. Comparisons of the evolutions of $c\cos\beta^*$ *versus* a for: i) the 170 single-crystal structure refinements of 1*M* samples (open circles), on two different expanded scales (top and bottom); and ii) the 75 synthetic samples investigated by powder X-ray diffraction in this thesis (filled squares with error bars). The solid lines correspond to $(c/a)\cos\beta^* = 1/3$.

6.4 Comparative analysis of single-crystal and synthetic powder samples

In this section, crystal chemical quantities calculated from the lattice parameters of synthetic powder samples (reported in Section 5.2) are compared to measured properties in single-crystal 1*M* structures. In accordance with the findings of the previous section, all calculations are based on a geometric homo-octahedral crystal structure model having no tetrahedral corrugation.

For the purpose of comparisons, single-crystal 1*M* samples were categorized into groups (see Appendix P) depending on the chemical compositions of the samples. There are four groups of single-crystal samples with compositions similar to our powder samples: i) sixty-seven biotite samples close to the annite-phlogopite join with $Al_{apfu} \leq 1.3$[1], labelled as '[Ann-Phl]'; ii) thirty-nine biotite samples more towards the eastonite-syderophyllite join with $Al_{apfu} > 1.3$, labelled as 'aluminous-[Ann-Phl]'; iii) twelve tetra-ferri biotite samples with $\langle Fe^{3+} \rangle_{apfu} > 0.4$), labelled as 'tetra-ferri-[Ann-Phl]'; and iv) two oxy-biotite samples (Nos. 27 and 53), labelled as 'oxy-Bt'.

6.4.1 Cation-specific bond lengths

The cation-specific octahedral and tetrahedral bond lengths used in this work to extract structural information from lattice parameters are given in Table 6.6. The procedure employed to establish these bond lengths is explained in this subsection, whereas the case of interlayer-site bond lengths is addressed in Subsections 6.4.4.

Figure 6.73 compares the values of average octahedral sheet bond length <M-O> (defined in Eq. 6.30) observed for the 170 single-crystal refinements of 1*M* structures (tabulated in Appendix P) to the following quantities: i) values of the mean octahedral bond length $\langle d_o \rangle^{Shannon}$ calculated using a set of bond lengths obtained from the tables of ionic radii given in [Shannon 1976] (Table 6.6); and ii) values of the mean octahedral bond length $\langle d_o \rangle^{Weiss}$ calculated using the cation-specific bond distances of [Weiss *et al.* 1992] averaged for *cis* and *trans* occupancies (Table 6.6).

Values of $\langle d_o \rangle^{Shannon}$ and $\langle d_o \rangle^{Weiss}$ were obtained from the chemical compositions (tabulated in Appendix P) reported for each sample as follows:

$$\langle d_o \rangle^{\text{Shannon or Weiss}} = \sum_i d_i(M) \cdot x_i \quad . \tag{6.50}$$

---

[1] X_{apfu} = number of atoms X per formula unit.

In the above equation, the symbols have the following meanings: i) the subscript '*i*' denotes a particular cation; ii) $d_i(M)$ refers to a cation-specific octahedral bond length; and iii) x_i represents the atomic fraction of cation *i* contained in the octahedral sites of a given sample. In the calculation of $<d_o>^{Shannon}$, the vacancy bond length value of Weiss was taken. Similarly, for $<d_o>^{Weiss}$, the $d_i(M)$ values of Shannon were used if there were no bond length provided by [Weiss *et al.* 1992] for given cations.

Values of $d_i(M)$ for Weiss and Shannon bond lengths are given in Table 6.6. For the sake of comparison, cation-specific *M-O* distances computed by the bond-valence parameters of [Brown & Altermatt 1985] are also presented in Table 6.6. Note that Shannon and Brown cation-specific bond lengths are equal to within 0.001 – 0.012 Å. In Figure 6.73, the data points display a poor agreement with the 1:1 correspondence solid lines that are shown. A similar poor agreement is observed if Brown's cation-specific $d_i(M)$ bond lengths are considered instead (not shown).

Figure 6.74 compares the evolutions of the average octahedral bond length <M-O> as a function of $<d_o>^{Shannon}$ for single-crystal structure refinements of: i) twenty-seven well characterized olivine samples with variable chemical compositions in the octahedral sites, $(Ni,Mg,Co,Fe)_2SiO_4$ [Myake *et al.* 1987; Böstrom 1987; Lager & Meagher 1978; Morimoto *et al.* 1974; Birle *et al.* 1968; Smyth 1975; Smyth & Hazen 1973; Rajamani *et al.* 1975; Hazen 1976, 1977; Nord *et al.* 1982]; and ii) six end-member trioctahedral mica samples having substitutions in the octahedral sheets, $\{K\}[Ni,Mg,Co]_3<AlSi_3>O_{10}(OH)_2$ [Redhammer & Roth 2002; Redhammer pers. comm.]. Single-crystal refinements of 1*M* structures belonging to the [Ann-Phl], aluminous-[Ann-Phl], tetra-ferri-[Ann-Phl], and oxy-Bt groups are also shown.

In examining Figure 6.74, one observes that olivine and [Ni, Mg, Co]-end-member mica samples fall on two distinct lines whose slopes differ from that of the 1:1 correspondence solid lines that are shown. In contrast, no clean trend can be discerned for the 1*M* structures, other than the fact that Shannon cation-specific bond lengths definitively over evaluate the mean octahedral bond length in the region between Mg^{2+} and Fe^{2+}, and vice-versa for many samples with an <M-O> size smaller than Mg^{2+}. Given that <M-O> values of well-characterized olivine and end-member mica samples vary linearly — as expected over a small range of average bond lengths — with the $<d_o>^{Shannon}$ values, the scatter observed for the 1*M* structures is attributed to uncertainties in the chemical compositions of these samples.

The dashed lines drawn in Figure 6.74 correspond to a linear regression through the six [Ni, Mg, Co]-end-member trioctahedral mica samples (samples not shown), that were used to establish the cation-specific octahedral $d_i(M)$ values for Ni^{2+}, Mg^{2+}, and Co^{2+} specified in Table

6.6. The errors of these cation-specific bond lengths were obtained from the linear regression analysis results using standard error calculation procedures.

In the case of Fe^{2+}, Fe^{3+}, and Al^{3+} cations, the adopted cation-specific bond lengths are the mid-points between the values predicted by Shannon bond lengths (solid lines) and the ones yielded by the linear regression described above (dashed lines). The individual errors on these cation-specific bond lengths are estimated by taking half of the difference between two corresponding values for a given cation. The corresponding values are given in Table 6.6.

Let us now turn to tetrahedral bond lengths. Figure 6.75 presents the average basal tetrahedral bond length $\langle T\text{-}O\rangle_{bas}$ as a function of the reported Si_{apfu} (where X_{apfu} = number of atoms X per formula unit), along with the distribution of Si_{apfu} values for the 170 single-crystal samples. In examining this figure, the first observation is that only 10 % of the structures (17 out 170) have a near-ideal annite-phlogopite Si_{apfu} value of ~3. Moreover, there appears to be no simple relationship between $\langle T\text{-}O\rangle_{bas}$ and $[Si]_{apfu}$, presumably due to the fact that the tetrahedral sheets contain not only Si^{4+}, but also other cations such as Al^{3+}, Fe^{3+}, and Ti^{4+}, in different amounts.

Given the above situation, cation-specific basal tetrahedral bond lengths were determined as follows. In Figure 6.75, the black squares represent the $T\text{-}O_{bas}$ distances that were assumed for $\langle Al_{1.1}Si_{2.9}\rangle$, $\langle FeSi_3\rangle$, and $\langle Al_{2.8}Si_{1.2}\rangle$ tetrahedral sheets (Table 6.6). The $T\text{-}O_{bas}$ and Si_{apfu} values adopted for $\langle Al_{1.1}Si_{2.9}\rangle$ and $\langle FeSi_3\rangle$ correspond to, respectively: i) the average $T\text{-}O_{bas}$ value of the [Ni, Mg, Co]-end-member mica samples referred to above [Redhammer & Roth 2002; Redhammer pers. comm.]; and ii) the $\langle T\text{-}O\rangle_{bas}$ value of the synthetic tetra-ferri-annite sample of [Donnay *et al.* 1964a]. In the case of $\langle Al_{2.8}Si_{1.2}\rangle$, the adopted $T\text{-}O_{bas}$ distance corresponds the average $\langle T\text{-}O\rangle_{bas}$ and Si_{apfu} values that one obtains from this cluster of samples.

Values of cation-specific basal tetrahedral bond length $d_t^{bas}(T)$ were then derived by solving the set of three linear equations given by combining the assumed $T\text{-}O_{bas}$ distances and chemical compositions for $\langle Al_{1.1}Si_{2.9}\rangle$, $\langle FeSi_3\rangle$, and $\langle Al_{2.8}Si_{1.2}\rangle$ tetrahedral sheets. The values of $d_t^{bas}(T)$ hence acquired for Si^{4+}, Al^{3+}, and Fe^{3+} are compiled in Table 6.6; in Figure 6.75, the open square represents the value of $d_t^{bas}(T)$ thus predicted for Si^{4+}. For the sake of comparison, an appropriate set of bond lengths computed from the tables of ionic radii of [Shannon 1976] is also presented in Table 6.6. No error evaluation was attempted for the cation-specific tetrahedral bond lengths, but bond lengths consistent with Shannon values were also tested.

cation-specific octahedral bond lengths (Å) $d_t(M)$

The vertical dotted lines correspond to $[Si]_{apfu} = 3$. See text for a detailed explanation of the content of this figure.

6.4.2 *b* as a function of the mean octahedral bond length

Figures 6.76 and 6.77 show *b versus* the mean octahedral bond length, [D], calculated for various solid solution series studied in this thesis, whereas Figures 6.78 and 6.79 display *b* as a function of the average octahedral sheet bond length <M-O> for the various groups of single-crystal 1*M* samples. Some octahedral flattening $\psi = constant$ (dotted lines) and octahedral sheet height $h_o = constant$ (dashed lines) predictions made via Eq. 6.12 (Subsection 6.2.2) — that are valid for both *geometric homo-octahedral* and *geometric meso-octahedral* ideal octahedral sheet models — are shown as reference in these figures.

For a given sample, [D] is calculated as in Eq. 6.50 using the cation-specific octahedral bond lengths of Table 6.6, the nominal composition of the sample (Eqs. 3.1-3.4, 3.6, and 3.9; Table 3.1), and the measured ferric and ferrous iron site populations obtained from Mössbauer spectroscopy (Table 3.3, Section 3.5), assuming that any amounts of tetrahedral ferric iron <Fe^{3+}> occurs through Al/Fe exchange between octahedral and tetrahedral sheets (i.e., via Eq. 1.4). In the case of the annite-oxyannite-ferrioxyannite series, following [Rancourt *et al.* 2001], annite-oxyannite ($Fe^{2+} + OH^- \rightleftharpoons Fe^{3+} + O^{2-} + H\uparrow$; Eq. 1.1) and oxyannite-ferrioxyannite ($3\ Fe^{2+} \rightleftharpoons 2\ Fe^{3+} + {}^{[6]}\square + Fe\uparrow$; Eq. 1.2) stoichiometries were assumed at $T_{TR} \leq 350$ °C and $T_{TR} \geq 370$ °C, respectively.

As illustrated in Figure 6.77, the differences in crystal chemical behaviours seen in Figure 6.76 between the "divalent" (Co-Mg JLR, Mg-Ni JLR, Fe-MgJLR, Fe-Mg RGBn, and Fe-Ni GR) and "trivalent" (Ann-oxy-ferrioxy and Fe-Mg RGBr) solid solution series do not depend on the particular values of cation-specific octahedral bond lengths that are assumed. The error bars displayed along the *x*-axis of Figure 6.77 represent the maximum variations in [D] values obtained for each sample using the individual errors of the cation-specific $d_i(M)$ values given in Table 6.6.

Moreover, as explained in [Rancourt *et al.* 2001], the break observed in the behaviour of the Ann-oxy-ferrioxy series between $T_{TR} = 350$ and 370 °C occurs irrespective of any particular stoichiometries assumed for these samples. That is, any combination of the oxybiotite reaction ($Fe^{2+} + OH^- \rightleftharpoons Fe^{3+} + O^{2-} + H\uparrow$; Eq. 1.1) and the Fe vacancy substitution ($3\ Fe^{2+} \rightleftharpoons 2\ Fe^{3+} + {}^{[6]}\square + Fe\uparrow$; Eq. 1.2) gives a discontinuity such as the one shown in Figures 6.76 and 6.77.

One notes that the positions of the solid-solution lines of the divalent series move progressively from $\psi = 58.5°$ to higher $\psi = constant$ angle predictions as the Fe^{3+}/Fe^{2+} ratio of the given series increases (see Table 3.3, Section 3.5). This is clearly shown in Figure 6.80, where calculated flattening angle $\psi_{calculated}$ values (via Eq. 6.12, Subsection 6.2.2) are plotted as a

function of [D] .

By contrast, Figures 6.81 and 6.82 show that in 1*M* single-crystal samples, the average flattening angle <ψ> always decreases with increasing average octahedral bond length <M-O>, within a given solid solution series or a particular group of samples. For samples with chemical compositions similar to our synthetic powder samples, the range of <ψ> values observed is closely delimited by the values of $\psi_{calculated}$ that were obtained for the Ni-Mg JLR, Co-Mg JLR, and Ann-oxy-ferrioxy solid solution series (Figure 6.81).

In examining Figure 6.81 attentively, one notes a higher degree of correlation between <ψ> and <M-O> for [Ann-Phl] samples, as compared to other pertinent groups of single-crystal samples. Similarly, Figures 6.83 and 6.84 show that the individual octahedral-site flattening angles ψ_{M1} and ψ_{M2} also increase with decreasing <M1-O> and <M2-O> distances. However, one observes that the correlation is higher for *M*2 than for *M*1 sites. [Redhammer & Roth 2002] and [Brigatti et al. 1991] have also made similar observations.

The above trends, in terms of an increasing flattening as the bond length decreases, do not appear to be present in our synthetic divalent solid solution series on the basis of the bond lengths that were considered (Table 6.6). This is puzzling and could indicate an important difference between natural single-crystal and synthetic powder samples. Note however that the *b* *vs.* [D] (Figure 6.76) behaviour of the synthetic Al-rich Fe-Mg RGBr series has a slope similar to the one observe in the plot of *b vs.* <M-O> (Figure 6.78) for natural [Ann-Phl] single-crystal samples.

As revealed in Figures 6.83 and 6.84, the effect that high-charge cations (such as Al^{3+}, Fe^{3+}, and Ti^{4+}) may induce in the octahedral sheets of micas seems to play an important role. This has been the subject of many studies, where the authors have mainly attempted to establish links between various measured structural parameters and the chemical compositions of the samples (e.g., see [Alietti *et al.* 1995, 1997; Brigatti & Guggenheim 2002; Brigatti & Poppi 1993; Brigatti *et al.* 1991, 1996a, 1996b, 1998, 2000a, 2000b, 2001; Cruciani & Zanazzi 1994; Redhammer *et al.* 2000; Redhammer & Roth 2002]).

More work is required to fully understand the results presented in this subsection. Finally, as will be discussed below, the plateau in *b* values observed for the Mg-Ni JLR series Figures 6.76-6.78) is attributed to a maximum limit of the tetrahedral rotation angle for trioctahedral K-rich micas having an $<Al_1Si_3>$ tetrahedral sheet.

6.4.3 Tetrahedral rotation limits

Figure 6.85 displays the average basal edge length $\langle O\text{-}O\rangle_{bas}$ as a function of the average basal tetrahedral bond length $\langle T\text{-}O\rangle_{bas}$ for the 170 single-crystal samples. The lines (solid, dashed, and dotted) that are shown in this graph correspond to tetrahedral flattening O_{bas}-T-O_{bas} angle $\tau_{bas} = constant$ predictions made via Eq. 6.15 (Subsection 6.2.4). One observes that the $\{K\}\langle Al_{\sim 1}Si_{\sim 3}\rangle$ samples closely follow the $\tau_{bas} = 108.5°$ solid-line prediction, whereas other groups of samples having different tetrahedral sheet contents cluster at other particular positions.

Figure 6.86 shows the tetrahedral rotation angle, $\alpha_{calculated}$, as a function of the octahedral-to-tetrahedral cation-oxygen bond length ratio, $[D]/\langle T\rangle_{bas}$, for various solid solution series of synthetic powder samples studied in this thesis. $\langle T\rangle_{bas}$ is the mean basal tetrahedral bond length calculated in the same manner as for [D] via Eq. 6.50 (see Subsection 6.2.4). For a given sample, $\alpha_{calculated}$ is obtained from the (measured) b and (calculated) $\langle T\rangle_{bas}$ values via substitution of Eq. 6.15 into 6.19, assuming that $\tau_{bas} = 108.5°$ (Figure 6.85).

The various predictions that are displayed as thin solid lines in Figure 6.86 are obtained by equating Eqs. 6.12 and 6.15 (Subsection 6.2.4) at a given octahedral flattening angle ψ with $\tau_{bas} = 108.5°$ (Figure 6.85). As illustrated by the positions of the small arrows that are drawn, the point of initiation of the lower limit on α moves progressively from lower to higher $[D]/\langle T\rangle_{bas}$ ratio, which depends on both octahedral ψ and tetrahedral τ_{bas} flattening angles that are assumed in the calculations.

The lower limit on α corresponds to the point where the tetrahedral sheets cannot laterally fit on top of the octahedral sheets. On the basis of the structural parameters that were taken to occur for octahedrons and tetrahedrons in the above described calculations, one sees that all the Fe-end-member synthetic samples fall in a regime where octahedral and tetrahedral sheets cannot be matched, as predicted by [Hazen & Wones 1972, 1978].

In Figure 6.86, a higher limit on α seen for the Mg-Ni JLR series occurs irrespective of any set of cation-specific basal tetrahedral bond lengths taken between Shannon values (Table 6.6) and the ones determined in this thesis (Table 6.6, Figure 6.85, Subsection 6.2.1). The only difference is that one obtains different *plateau* values for α. Here, with the structural parameters that are assumed, one calculates a higher limit on $\alpha \cong 9.5°$.

Figures 6.87 and 6.88 show the average tetrahedral rotation α as a function of the ratio $\langle M\text{-}O\rangle/\langle T\text{-}O\rangle_{bas}$ for the single-crystal samples on an overall and expanded scale, respectively. The dashed-dotted horizontal lines displayed in these figures are drawn at the same α positions as those illustrated in Figure 6.86. Note also that Figure 6.88 has the same scale as Figure 6.86.

In examining Figure 6.88, one sees that the density of the data points is higher near the dashed-dotted line positioned at $\alpha = 9.5°$. [Redhammer & Roth 2002] have made similar observations by plotting the average tetrahedral rotation angle α as a function of the mean octahedral cation radii, calculated using the tables of [Shannon 1976], for a subset of single-crystal 1*M* samples considered in this thesis.

Figures 6.89 presents the distribution of α for all single-crystal 1*M* structures. One observes the distribution to be clearly asymmetric. All samples outside the main trend displayed by the biotite samples belong to groups that have significantly different tetrahedral-sheet contents, except for paragonite which is a dioctahedral mica.

Figures 6.90 shows the the distributions of α for the [Ann-Phl], aluminous-[Ann-Phl], and tetra-ferri-[Ann-Phl] groups separately. Overall, Figure 6.90 demonstrates strong evidence that, indeed, a higher limit appears to be present at $\alpha \cong 9.5°$ for the [Ann-Phl] samples. Morever, as discussed by [Hazen & Wones 1978], Figure 6.90 presents strong evidence for the proposed higher limit on α to be tetrahedral composition dependent

Whereas the lower limit on α is understood as arising from a lateral misfit between octahedral and tetrahedral sheets, the higher limit on α cannot be attributed to a structural mechanisms based on the geometrical models that were tested. Therefore, the higher α-limit is tentatively attributed to some combination of intra-tetrahedral-sheet inter-cation repulsion and local bonding constraints on tetrahedrons.

From the results of this subsection, one concludes that: i) an O_{bas}-T-O_{bas} angle of 108.5° is favoured for an $<Al_1Si_3>$ tetrahedral sheet; and ii) strong evidence supports that the break in b seen in the Mg-Ni JLR series is due to a higher limit of tetrahedral rotation for an $<Al_1Si_3>$ sheet of ~9.5° .

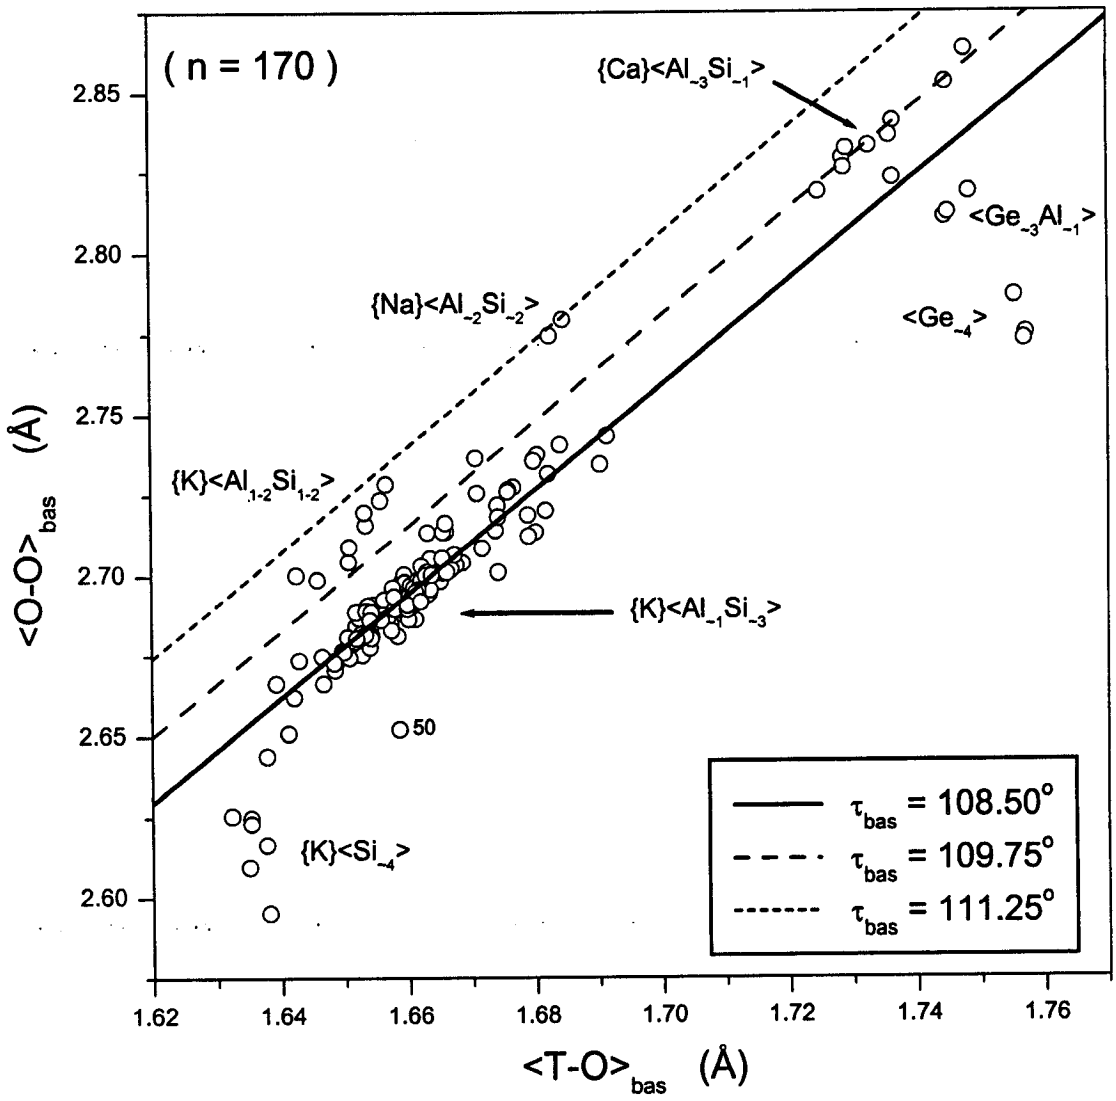

Figure 6.85. Average basal edge length $\langle O\text{-}O\rangle_{bas}$ as a function of the average basal tetrahedral bond length $\langle T\text{-}O\rangle_{bas}$ for the 170 single-crystal samples. The various lines correspond to predictions that are explained in the text.

6.4.4 Interlayer bond lengths and interlayer spacings

From an appropriate combination of equations described in Section 6.2:

i) Eqs. 6.3 and 6.12 for octahedral sheets;
ii) Eq. 6.16 (ideal tetrahedron) or Eq. 6.17 (iso-bond-basal-flattened tetrahedron) or Eq. 6.18 (aniso-bond tetrahedron), and Eq. 6.19 for tetrahedral sheets;
iii) Eq. 6.25 for interlayer spacing d_{int}; and
iv) Eq. 6.21 for lattice parameter c;

one can adjust the inner interlayer bond length to the measured c for a given synthetic sample.

In the results that are presented in this subsection, only iso-bond-basal-flattened tetrahedrons were considered in testing.

Figure 6.91 shows the adjusted inner interlayer bond length, $(A\text{-}O)_{in}^{adjusted}$, as a function of the lattice parameter a, for various solid solution series of synthetic powder samples. On the same graph, Figure 6.91 also displays the average inner interlayer bond length, $\langle A\text{-}O\rangle_{in}$, as a function of a for pertinent groups of single-crystal samples. For the Al-rich Fe-Mg RGBr series, Figure 6.91 presents results obtained by assuming two different values of the O_{bas}-T-O_{bas} angle (τ_{bas} = 108.5° and 109.5°), whereas τ_{bas} =108.5° for other solid solution series. In these figures, one notes a complicated behaviour that is hard to understand.

A similar complicated behaviour is observed in Figure 6.92, where calculated interlayer spacing $d_{int}^{calculated}$ and interlayer spacing d_{int} are plotted as function of a, for synthetic powder and pertinent single-crystal samples, respectively.

On the other hand, Figure 6.93 and 6.94 show a linear correlation between: i) the average inner interlayer bond length $\langle A\text{-}O\rangle_{in}$ as function of the average tetrahedral rotation, α, observed for the 170 single-crystal biotite-1M samples (Figure 6.93); and ii) the adjusted inner interlayer bond length, $(A\text{-}O)_{in}^{adjusted}$, as a function of the calculated tetrahedral rotation angle, $\alpha_{calculated}$, for various solid solution series of synthetic powder samples (Figure 6.94).

From this subsection, therefore, one concludes that for a given interlayer cation species, the inner interlayer bond length monotonously increases as the tetrahedral rotation angle α decreases.

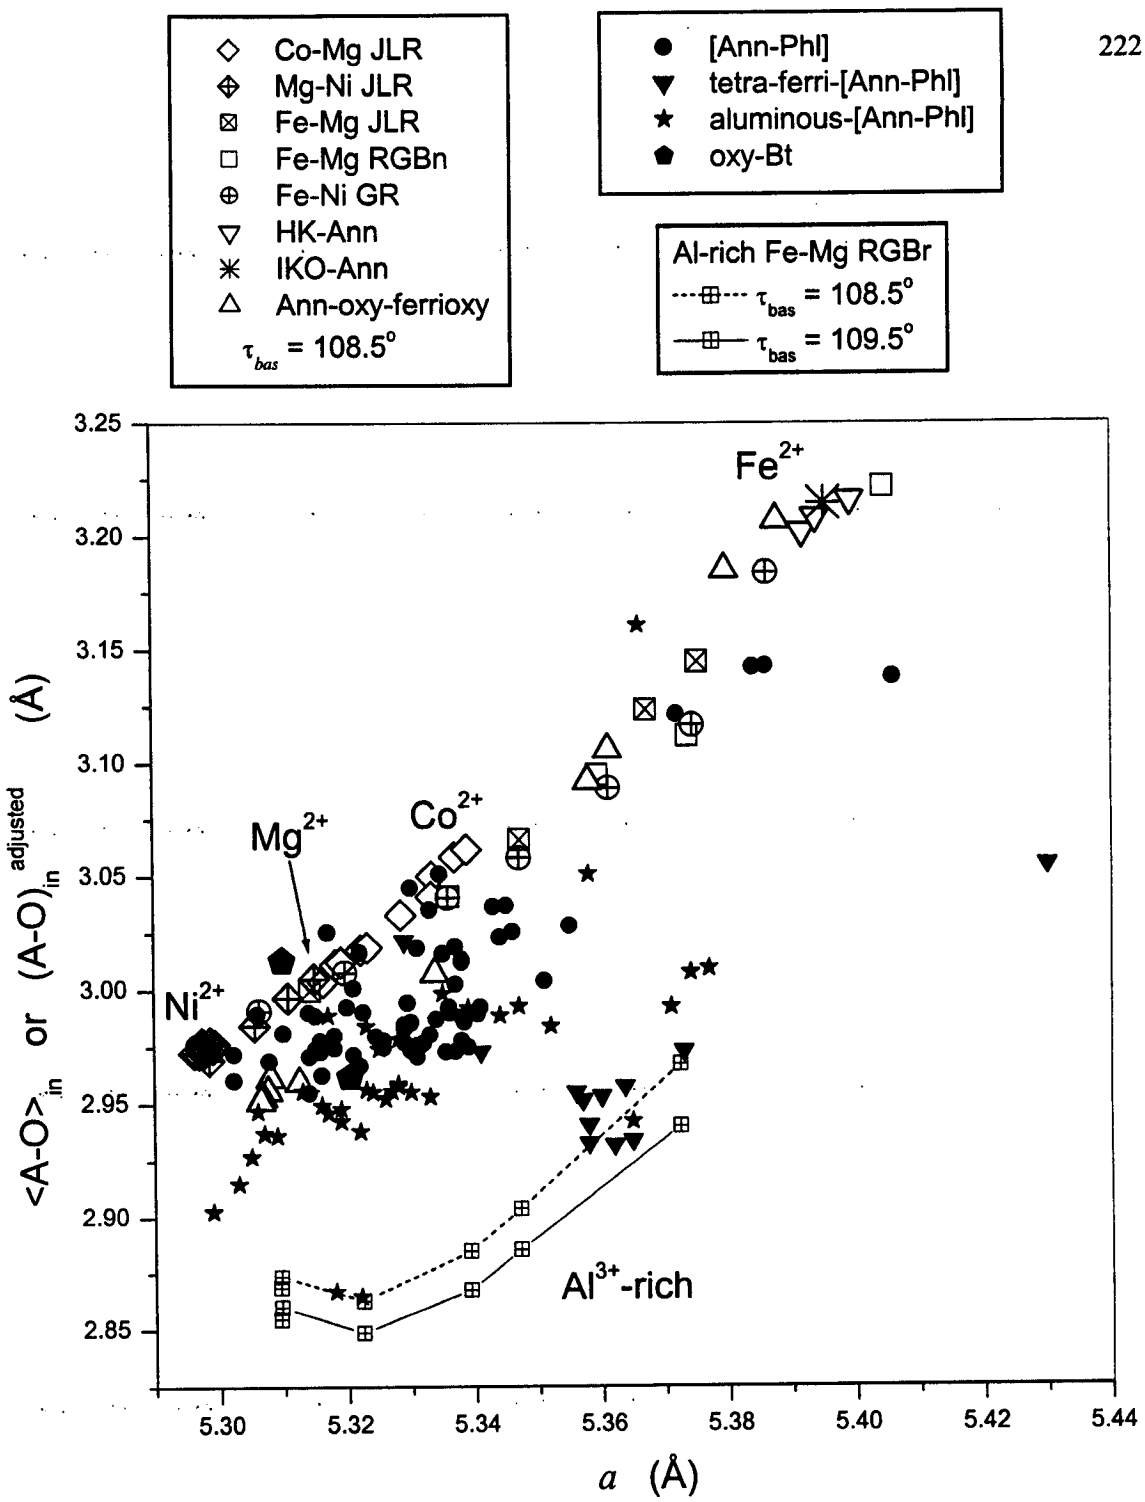

Figure 6.91. Adjusted inner interlayer bond length, $(A\text{-}O)_{in}^{adjusted}$, as a function of the lattice parameter a, for various solid solution series of synthetic powder samples. Also shown is the average inner interlayer bond length, $\langle A\text{-}O\rangle_{in}$, as a function of a for pertinent groups of single-crystal samples.

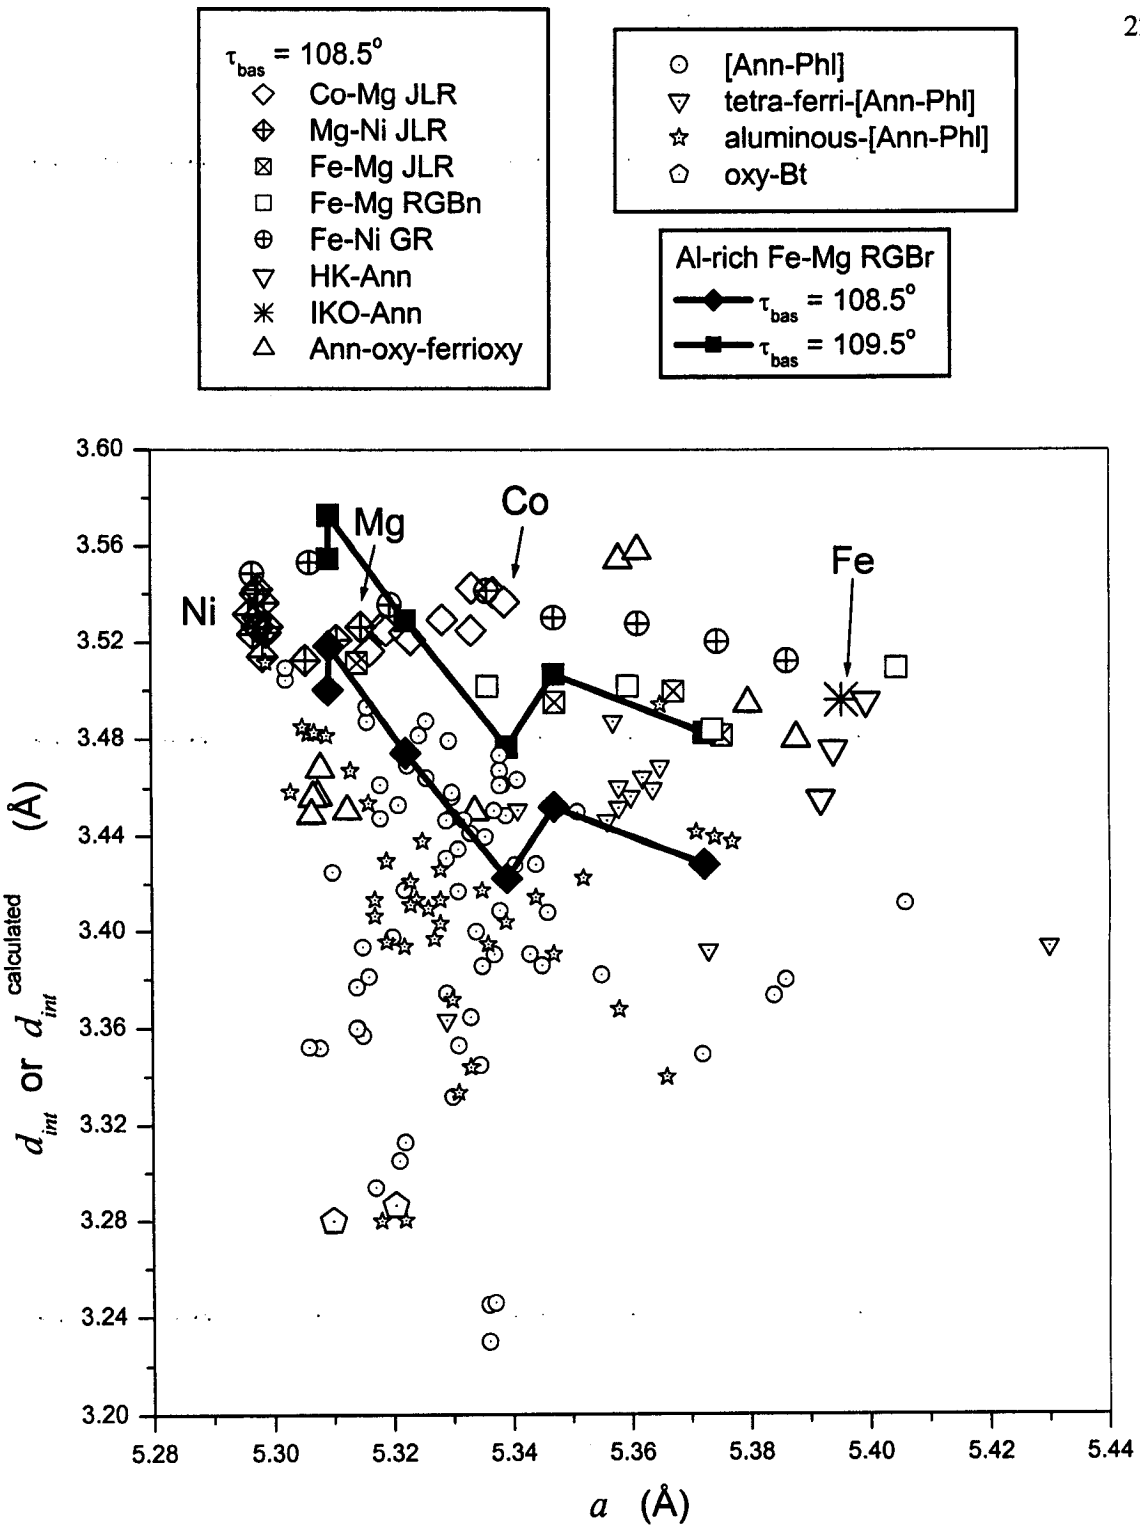

Figure 6.92. Calculated interlayer spacing, $d_{int}^{\text{calculated}}$, and interlayer spacing, d_{int}, as functions of a, for synthetic powder and single-crystal samples, respectively.

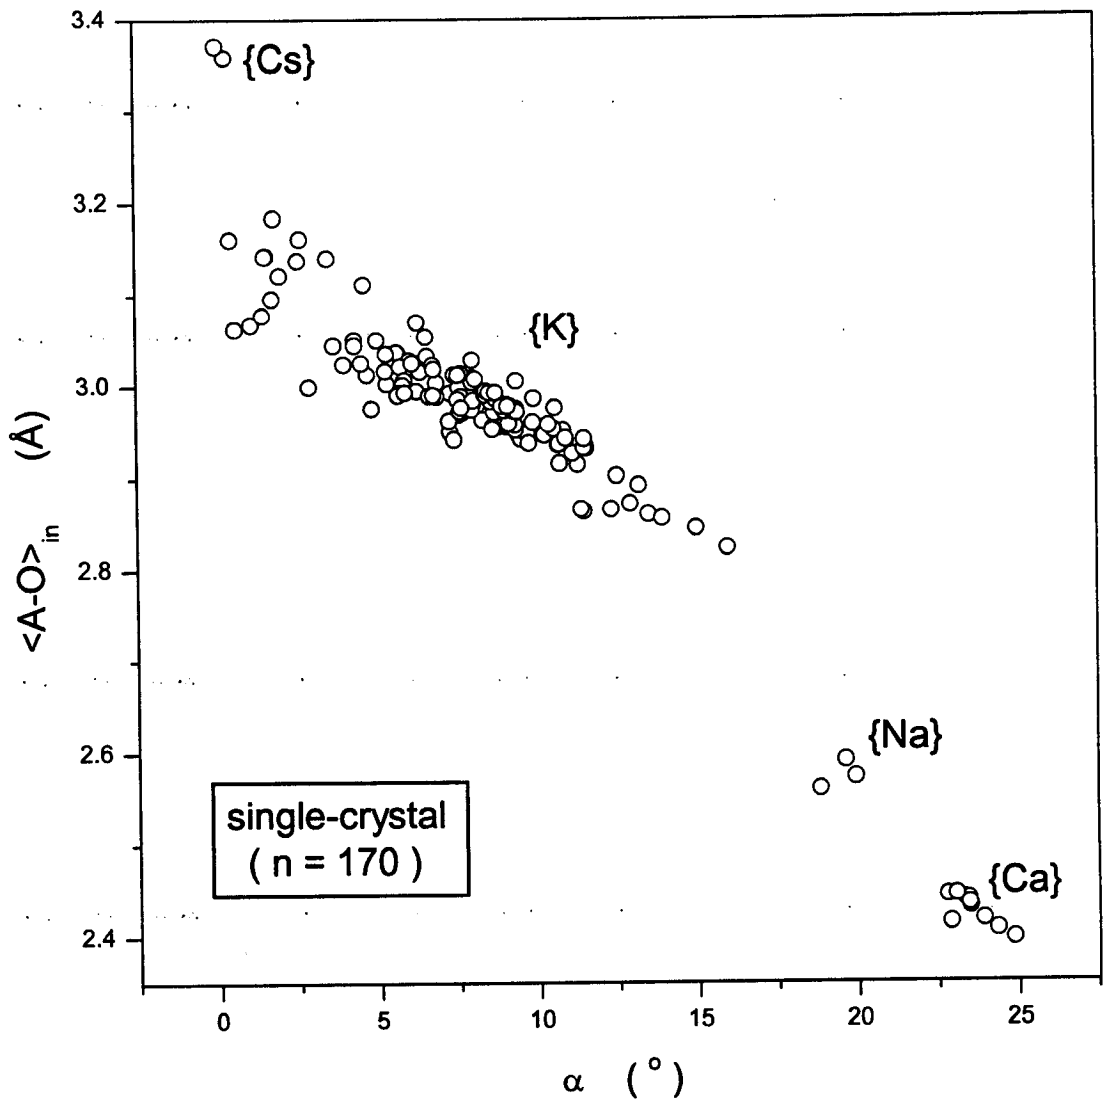

Figure 6.93. Average inner interlayer bond length $\langle A\text{-}O\rangle_{in}$ as function of the average tetrahedral rotation, α, observed for the 170 single-crystal 1*M* samples.

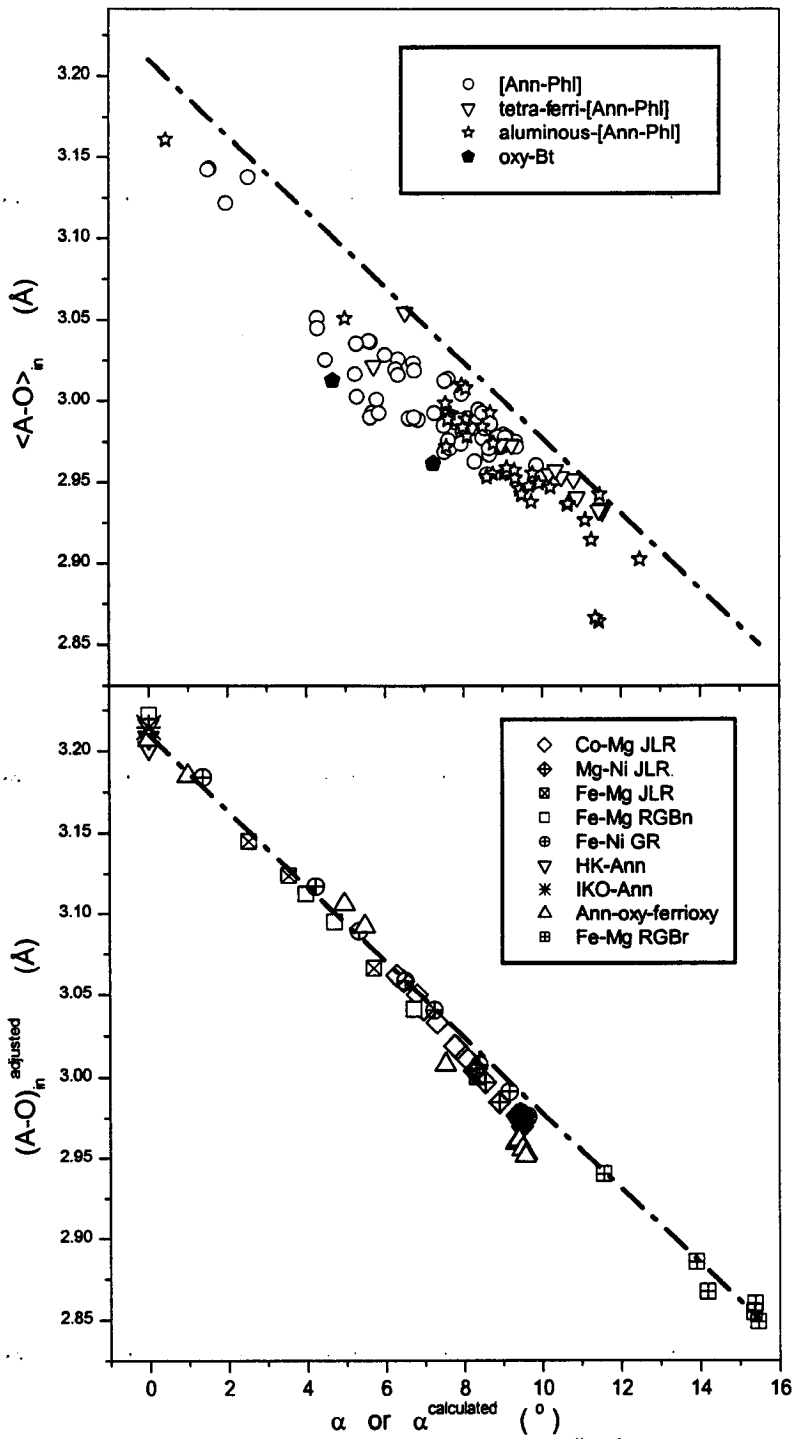

Figure 6.94. Adjusted inner interlayer bond length, $(A\text{-}O)_{in}^{adjusted}$, as a function of the calculated tetrahedral rotation angle, $\alpha_{calculated}$, for various solid solution series of synthetic powder samples. Also shown are inner interlayer bond length, $\langle A\text{-}O\rangle_{in}$, as function of the average tetrahedral rotation, α, for the [Ann-Phl], aluminous-[Ann-Phl], and tetra-ferri-[Ann-Phl] groups of single-crystal samples.

Chapter 7. Discussion

7.1 Rationale of the crystal chemical approach

The ultimate crystal chemical model would predict exactly the atomic coordinates of all atoms in the average unit cell, given the stoichiometry and degree and type of any chemical order. In trioctahedral micas, the large chemical variability of the octahedral, tetrahedral, and interlayer sites complicates the modelling of the crystal structure, as does the inherent misfit between the constituent octahedral and tetrahedral sheets. Moreover, the different crystallographically distinct cationic sites may be occupied by different ion populations either in an ordered or a disordered way, Al^{3+} and Fe^{3+} (and Ti^{4+} ?) may populate both octahedral and tetrahedral sites, and Fe and Mn may be present in different oxidation states (Fe^{2+} and Fe^{3+}; Mn^{2+} and Mn^{3+}). To account for all this complexity, an approach based on a simple conceptual framework is therefore highly desirable.

Following the main premiss of crystal chemistry, we assume that the average cation-anion bond length of a given crystallographically distinct cationic site in the average unit cell is a precise measure of the average chemical composition of that site and its coordinating anions. In contrast, chemical data obtained by electron microprobe analysis (and other analytic methods) are often incorrect because oxidation states, water (hydrogen), and light elements (such as Li) are not directly measured. Nonetheless, all subtleties pertaining to the average cationic contents, the geometries, and the dimensions of the different coordinating polyhedrons in the average unit cell of a given crystallographic structure are reflected in the measured diffraction intensities analysed in a structural refinement.

Consequently, we have adopted an approach where cation-specific bond lengths are used to predict the average bond sizes of the different cationic sites in octahedral and tetrahedral sheets (Subsection 6.4.1), while in the case of interlayer sites, we admit and show that the bond length of a given interlayer cationic species monotonously varies with the tetrahedral rotation angle (see Subsection 6.4.4, as well as Section 7.5 below). In this way, the average bond length of a given cationic site stems directly from its average chemical (cationic) composition.

In the various crystallographic structures of micas, the polyhedrons hosting the cations actually differentiate their bond lengths and angles in different ways depending on the space-group type and the polytype. These adjustments are understood to arise from, at least in part,

internal strains, connected with the presence of chemical composition differences from one unit cell to another in the crystal and to the structural misfit between tetrahedral and octahedral sheets, that depend on temperature and pressure [Ferraris & Vivaldi 2002; Bailey 1984a; Zanazzi & Pavase 2002].

For the above reasons, it is a well known fact that geometric crystal chemical models based on site-specific (uniform) cation-anion bond lengths only approximately give the atomic positions obtained in actual crystal structure refinements of micas. However, the extent to which such models are valid had never been determined or exploited to the extent presented here.

In the remaining of this chapter, we now discuss the main findings that were made following our approach founded on geometric crystal chemical models.

7.2 Fundamental difference between natural and synthetic trioctahedral-1*M* micas: geometric meso-octahedral versus geometric homo-octahedral sheets.

Based on the powder X-ray diffraction measurements of many solid solution series of synthetic powder samples (between Mg, Ni, Co, and Fe end members, with different degrees of oxidation, vacancy, and Al/Si contents, and including an OH/F substitution series; 75 samples indexed as 1*M* polytype, space-group type *C*2/*m*) and on the published crystal structures of 170 trioctahedral-1*M* micas (refined in space-group type *C*2/*m*) comprising both (42) synthetic and (128) natural single-crystal samples, we have shown that the relation

$$(c/a)\cos\beta^* = 1/3$$

holds exactly (within experimental error) for all synthetic powder samples (Figure 6.72, Subsection 6.3.6) whereas it does not hold in general for the natural or synthetic single-crystal samples (Figures 6.69-6.71, Subsection 6.3.6). This relation is not imposed by the *C*2/*m* space-group symmetry.

The $(c/a)\cos\beta^* = 1/3$ relation holds in the crystal structure model proposed by Donnay *et al.* [Donnay *et al.* 1964a] for a 1*M* unit cell of *C*2/*m* space-group symmetry (Eq. 6.20, Subsection 6.2.6), that assumes a geometric homo-octahedral sheet of uniform height in which the bond lengths (and flattening angles) of all octahedral sites are *equal* (Subsection 6.2.2). On the other hand, as explained in Subsection 6.3.5, the $(c/a)\cos\beta^* = 1/3$ relation is not expected to

hold in general when the bond lengths of the *M*1 and *M*2 sites are *unequal* in a 1*M* structure of *C*2/*m* symmetry; the same conclusion was also reached by [Bailey 1984a] following a reasoning similar to ours. We have derived and rigorously validated the latter conclusion by considering the geometric meso-octahedral sheet model of [Evans 2001] (Subsection 6.2.3), which, assuming only a uniform octahedral sheet height, predicts site-specific bond lengths and flattening angles for the *M*1 and *M*2 sites, and a counter-rotation angle for the *M*2 site, δ_{M2}, that is uniquely determined by the bond length difference between the *M*1 and *M*2 sites.

In our analysis, the geometric meso-octahedral character of the 170 trioctahedral-1*M* single-crystals is also corroborated by several parameters of the structure refinements:

1) The normalized squared octahedral size difference $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$ variation with the counter-rotation angle δ_{M2} (Figure 6.32, Subsection 6.3.2) exactly (within experimental error) follows our geometric meso-octahedral sheet predictions (Eqs. 6.37 and 6.38, Subsection 6.3.2), for 169 out of 170 trioctahedral-1*M* single-crystals. The only exception corresponds to a norrishite sample that breaks the $b = \sqrt{3} \cdot a$ relationship (Figure 6.3, Subsection 6.1).

2) The normalized in-plane intra-layer displacements between atoms located above and below the octahedral-cation plane (Eqs. 6.49a-6.49e; Figures 6.61 and 6.62) evolve in fair agreement with geometric meso-octahedral predictions (Eqs. 6.35 and 6.48) as a function of the normalized in-plane size difference $[\langle M1\text{-}O\rangle \sin\psi_{M1} - \langle M2\text{-}O\rangle \sin\psi_{M2}]/a$ (Figures 6.63-6.67, Subsection 6.3.5).

We conclude that our synthetic powder samples (usually having particle diameters in the range 0.01-10 μm) are geometric homo-octahedral whereas single-crystals (typical size of 0.05×0.05×0.01 mm or larger) are geometric meso-octahedral. The synthetic powders appear not to have had the time to equilibrate into a minimal free energy state, possibly because average diffusion hoping times occurring in those syntheses (compared to synthesis times) are larger than under synthesis conditions that lead to single-crystals (e.g., fluxing agents used in single-crystal syntheses, geological conditions and large petrogenesis equilibration times of natural samples), whereas all the single-crystal samples have to some extent exploited the free energy advantage of sorting smaller and larger cations into distinct crystallographic sites in a (geometric) meso-octahedral sheet structure. These results suggest further experimental work in which the conditions for and kinetics of meso-octahedral chemical ordering could be studied.

7.3 Factors affecting octahedral sheets in trioctahedral-1*M* micas

Many authors have studied the geometry of cationic sites in the octahedral sheets of trioctahedral-1*M* micas (e.g., [Bailey 1984a; Toraya 1981; Lin & Guggenheim 1983; Weiss *et al.* 1985, 1992; Alietti *et al.* 1995, 1997; Brigatti & Davoli 1990; Brigatti & Poppi 1993; Brigatti *et al.* 1991, 1996b, 2000a, 2000b, 2001; Cruciani & Zanazzi 1994; Brigatti & Guggenheim 2002; Redhammer & Roth 2002]), but so far only a few researchers have emphasized the utility of geometrical models in assessing both the octahedral topology (i.e., the octahedral dimensions and the octahedral distortions) and the complex crystal chemistry of these minerals (e.g., [Hazen & Wones 1972; Hazen & Burnham 1973; Hazen & Finger 1982]).

The exact agreement (within experimental error) of the geometric meso-octahedral sheet model with observations in trioctahedral-1*M* micas of *C*2/*m* symmetry (Eqs. 6.37-6.38; Figure 6.32) permits the identification of two rigorous parameters to quantify or predict the effects of different octahedral cation ordering patterns in these structures: i) the normalized squared octahedral size difference, $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$, and ii) the counter-rotation angle of the *M*2 site, δ_{M2} .

The latter two parameters, uniquely related via Eq. 6.37, are dimensionless quantities free from peculiarities due to chemical substitutions. Noting that the flattening angles of *M*1 and *M*2 sites are given by Eq. 6.9, one then has that the flattening angle difference $[\psi_{M1} - \psi_{M2}]$ is also uniquely determined by one of the above parameters.

Several authors have noted correlations between differences of structural parameters characterizing the *M*1 and *M*2 sites in trioctahedral-1*M* micas of *C*2/*m* symmetry [Brigatti & Davoli 1990; Brigatti *et al.* 1991; Redhammer & Roth 2002; Lin & Guggenheim 1983; Alietti *et al.* 1997], but none of them have stressed that such relationships can be explained by geometrical models that admit site-specific uniform bond lengths for *M*1 and *M*2 sites in an octahedral sheet of uniform height. We have demonstrated this for the first time.

Weiss *et al.* [Weiss *et al.* 1985, 1992] have noticed high correlations by plotting absolute differences of ψ angles in a sheet — that is $|\psi_{M1} - \psi_{M2}|$, $|\psi_{M2} - \psi_{M3}|$, and $|\psi_{M3} - \psi_{M1}|$ — against corresponding differences of counter-rotation δ angles. They have also recognized that these correlations were the consequence of the octahedral sheet's uniform thickness but they have only derived linear regression equations that predict ψ and δ angles separately for each site, as functions of the mean bond lengths of the individual octahedral sites. Such an approach cannot possibly predict atomic coordinates correctly, because it does not properly take into account the constraints imposed by the uniform height of the octahedral sheet.

Using the geometric meso-octahedral and geometric hetero-octahedral sheet models of [Evans 2001], we suggest that rigorous geometrical relationships, similar to Eq. 6.37, could also be established for meso-octahedral and hetero-octahedral (dioctahedral or trioctahedral) mica structures of other space-group types and polytypes. The main advantage of the geometrical models of [Evans 2001] is that they directly (and correctly) predict the atomic coordinates in an octahedral sheet of uniform height as a function of site-specific uniform bond lengths, allowing rigorous parameters to be defined to follow octahedral chemical ordering.

The vast majority of the trioctahedral-1*M* micas considered (151 out of 170 samples) have <M1-O> > <M2-O> and $\psi_{M1} > \psi_{M2}$. This has been described as the normal ordering pattern [Toraya 1981; Bailey 1984a; Guggenheim 1984] in which enlargement of *M*1 with respect to *M*2 is believed to be caused by partitioning of high-charge, smaller cations into *M*2, while low-charge, larger cations and vacancies tend to occupy *M*1. This mode of ordering is in agreement with the propositions of [Hazen & Wones 1972], who suggested that octahedral flattening is primarily a function of the mean cation radius [R] inside an octahedron (where [R] is obtained using the cation-specific radii of [Shannon & Prewitt 1969, 1970; Shannon 1976]).

On the other hand, [Lin & Guggenheim 1983] argued that the flattening of each octahedral cationic site in an octahedral sheet is mainly dependent on the field strengths of the neighbouring sites, where the field strength of an individual site is equal to its valence divided by its mean cation radius. Alternatively, [Weiss *et al.* 1985] asserted that the flattening ψ and counter-rotation δ angles of any particular octahedron in a sheet are due to the interaction in the whole sheet rather than in the octahedron alone.

Our results give a different perspective to the above debate regarding the nature of octahedral flattening (cation-specific versus whole-sheet control?). We have shown that plots of lattice parameter *b* versus the average octahedral sheet bond length are particularly instructive and allow the following distinction to be made. Unoxidized synthetic divalent solid solution series (between Mg^{2+}, Ni^{2+}, Co^{2+}, and Fe^{2+}) tend to evolve along constant flattening angle lines as the mean octahedral bond length increases (Figure 6.76, Subsection 6.4.2), whereas trivalent octahedral cation (Fe^{3+} and Al^{3+}) and vacancy bearing synthetic solid solution series (Figure 6.76, Subsection 6.4.2) and natural biotite-1*M* single-crystals (Figure 6.78, Subsection 6.4.2) follow trends with decreasing flattening angles as the average bond length of the sheet increases (see also Figures 6.80-6.81, Subsection 6.4.2).

Given that the geometric homo-octahedral and geometric meso-octahedral sheet models both predict the same constant flattening-angle lines on a graph of *b versus* average-octahedral-bond-length and that both these models accurately predict *b* (Figures 6.30-6.31, Subsection

6.3.2), this means that the scatter in the plot of *b vs.* <M-O> for the biotite-1*M* single-crystals displayed in Figure 6.78 (Subsection 6.4.2) cannot be attributed to octahedral cation ordering, and hence must to a large extent be due to variations in the cationic compositions of the octahedral sheets, that cause different average octahedral flattening angles to occur.

The *b* versus mean-octahedral-bond-length behaviours of synthetic powder samples are consistent with the fact that natural Fe-rich micas tend to have greater octahedral Al^{3+} concentrations as compared to natural phlogopite crystals (e.g., see [Foster 1960; Redhammer & Roth 2002]). Substitution of Al^{3+} for divalent cations in the octahedral sheets of trioctahedral micas accompanies a corresponding substitution of Al^{3+} for Si^{4+} in the tetrahedral sheets. Thus excess Al^{3+} in the annite-phlogopite series has the dual effect of increasing the average bond size of the tetrahedral sheet, while decreasing the average octahedral bond length. Therefore, the octahedral sheets of trioctahedral-1*M* micas are also influenced by the octahedral-to-tetrahedral sheet mismatch, especially in the proximity of a tetrahedral rotation limit. This is discussed further in Section 7.5 below. In this way, a plot of *b versus* average-octahedral-bond-length is a particularly instructive data representation in assessing the average octahedral flattening that results from complex crystal chemical substitutions.

We conclude that the average octahedral flattening of trioctahedral-1*M* micas of *C*2/*m* symmetry is determined by both the octahedral cationic composition and the tetrahedral-to-octahedral sheet mismatch, whereas the individual flattening angles of *M*1 and *M*2 sites depend solely on the degree of octahedral *M*1/*M*2 chemical ordering which occurs. Our crystal chemical analysis is important because it provides rigorous analysis tools (*b vs.* <M-O> graph, $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$, δ_{M2}) to accurately follow key crystal chemical parameters (average octahedral flattening, 'geometric' octahedral ordering) that may affect the stability relationships of these micas. For example, the degree of octahedral ordering is an important factor contributing to the overall energy and the stability of a mica structure; this may have important consequences in the formulation of mica-based (single-mineral or multi-mineral) geothermometers and geobarometers [Cruciani & Zanazzi 1994].

7.4 Geometric meso-octahedral 2:1 layer silicates must have corrugated tetrahedral sheets composed of bond-distorted tetrahedrons

In its simplest form, the architecture of the TOT layers in micas and other 2:1 layer silicates is consistent with flat tetrahedral sheets lying on either sides of a flat octahedral sheet. This

assumption is made in most crystal chemical models of layer silicates by providing tetrahedral-to-octahedral sheet matching via tetrahedral rotation, that does not involve out of plane tetrahedral tilting in order to match a given octahedral sheet having some mean octahedral bond length and flattening angle.

Using tetrahedral sheet models involving coplanar basal equilateral faces rotated by a specified tetrahedral rotation angle α (Eqs. 6.15-6.19; Figures 6.8-6.11, Subsections 6.2.4 and 6.2.5) together with the geometric homo- and meso-octahedral sheet models of [Evans 2001] (Subsections 6.2.2 and 6.2.3), we have rigorously demonstrated that flat tetrahedral sheets having tetrahedral apical bonds perpendicular to the *ab*-plane are only possible in 2:1 layer silicates having a geometric homo-octahedral sheet (see explanations related to Figure 6.45, Subsection 6.3.3). This means that via unavoidable structural constraints, *a tetrahedral sheet comprised of coplanar equilateral triangular basal faces cannot be arranged to match a geometric meso-octahedral sheet.*

For a 1*M* structure of *C*2/*m* symmetry, we have shown that a straightforward means to accommodate a geometric meso-octahedral sheet is to have lowered (*M*1 > *M*2) or raised (*M*1 < *M*2) O1 atoms relative to (O2-O2') basal edges (Subsection 6.3.3). [Lee & Guggenheim 1981] and [Appelo 1978] have also recognized that basal-oxygen plane corrugation is an effective way to provide linkage between octahedral and tetrahedral sheets in the presence of differently sized octahedral sites, but they have not demonstrated that such corrugation *must* occur when there is *M*1/*M*2 chemical ordering.

Basal-oxygen plane corrugation (Δz) is small but significant in trioctahedral-1*M* micas of *C*2/*m* symmetry (Figure 6.29, Subsection 6.3.1; Figure 6.32, Subsection 6.3.2), whereas it is much larger in dioctahedral-2M_1 micas having space-group type *C*2/*c*, where usually the *M*1 site is vacant while Al^{3+} occupies the *M*2 site (e.g., see [Bailey 1984; Brigatti & Guggenheim 2002]). A good correlation is observed between Δz and the size difference of *M*1 and *M*2 sites (e.g., plot of $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$ *vs.* Δz , Figure 6.44, Subsection 6.3.3; see also [Brigatti & Guggenheim 2002]).

In addition, we have established that basal tetrahedral corrugation cannot simply be accomplished by cooperative tilting of tetrahedrons having a simple geometrical shape, as the tetrahedrons themselves *must* be distorted in the process such as to have isosceles or scalene triangular basal-oxygen faces (Figure 6.45, Subsection 6.3.3), which means that the tetrahedrons require unequal basal bond lengths arising from unavoidable structural constraints. Several tetrahedral distortion parameters of the 170 single-crystal 1*M* refinements also support these findings: i) the progressive widths of the distributions of sample-specific tetrahedral distortion

parameters that characterize the degree to which individual bond lengths, edge lengths, and bond angles differ within a given tetrahedron (Eqs. 6.39-6.39e, Table 6.4, Figures 6.39 and 6.46, Subsection 6.3.3); and ii) the strong correlation between Δz and the tetrahedral bending angle η between the apical bond and the pyramidal base formed by the three basal bonds (Figures 6.42 and 6.43, Subsection 6.3.3).

We conclude that geometric meso-octahedral 2:1 layer silicates must have corrugated tetrahedral sheets composed of bond-distorted tetrahedrons, as we expect similar arguments as those explained above to hold for all types of 2:1 layer silicates where geometric meso-octahedral sheets occur. Since tetrahedral corrugation develops in direct response to the degree to which the size of $M1 \neq M2$ and is well represented as such in the average unit cell, tetrahedral distortions due to corrugation are to be distinguished from local distortions due to local chemical variations caused by Al/Si disorder.

It has been proposed [Appelo 1978, 1979; Abbott & Burnham 1988] that basal-oxygen plane corrugation Δz may control the relative stability of $1M$ and $2M_1$ mica polytypes, the latter becoming energetically favoured when Δz increases. One also expects that the relative stability of mica polytypes is affected by Δz on geometric grounds by considering the interlayer cation configurations which result from Δz in the different homogeneous mica polytypes [Ferraris & Vivaldi 2002; Guven 1971; Takéuchi 1965]. Our results imply that the free energy advantage of sorting smaller and larger cations into differently sized $M1$ and $M2$ sites in a geometric meso-octahedral arrangement must be at least partly compromised by an energy increase associated with bond-distorted tetrahedrons. This could also be an important factor in determining the relative stability of $1M$ and $2M_1$ structures, the two most common mica polytypes.

7.5 Upper limit of tetrahedral rotation in trioctahedral-1*M* K-rich micas

Recently, [Redhammer & Roth 2002] have pointed out that a tetrahedral rotation of about 9.5° seems to be an upper limit for K-rich micas having an $<AlSi_3>$ tetrahedral-sheet composition. An upper limit of the tetrahedral rotation angle α had been proposed by [Hewitt & Wones 1975], who suggested that the size of the interlayer cation may control the maximum amount of tetrahedral rotation that can occur in a stable mica. The latter authors also suggested that the upper limit on α was the reason why Al-substitutions in synthetic biotite solid solutions cease at a tetrahedral composition of $<Al_{1.75}Si_{2.25}>$ and an octahedral composition of $[(Fe,Mg)_{2.25}Al_{0.75}]$ (which is approximately the compositions targeted in the Fe-Mg RGB Al-rich solid solution

series, see Table 3.1).

The crux of the argument of [Hewitt & Wones 1975] was based on calculated α-rotation angles and interlayer K-O bond lengths obtained using the nomogram of [Donnay *et al.* 1964] (their Figure 4), who assumed ideal tetrahedrons (and lattice parameter $\beta = 100°$) in their calculations. The α-rotation and K-O bond lengths that [Hewitt & Wones 1975] hence obtained for their most aluminous synthetic biotites ranged from 12° and 2.89 Å in their Mg-free samples to 14° and 2.77 Å in their Fe-free samples. Given that the accepted range of bond lengths for potassium in 6- to 12-fold coordination indicate that K-O bond lengths nearby the lower limit of 2.76 Å (6-fold) would be relatively unstable [Shannon & Prewitt, 1969, 1970; Shannon 1976], this then led these authors to propose that the interlayer site controls the maximum value of α and thus the maximum amount of Al-substitution, because Al-substitution in trioctahedral biotite enlarges the misfit between the octahedral and tetrahedral sheets and thereby increases the amount of necessary tetrahedral rotation α. However, tetrahedrons of actual biotite are not ideal and this strongly affects calculated α-rotation and interlayer bond lengths (e.g., [Takeda & Morosin 1975]).

The *O-T-O* angles of actual tetrahedrons are affected by both tetrahedral and interlayer contents [Takéuchi 1975; Brigatti & Guggenheim 2002] (see also Figure 6.40, Subsection 6.3.3). In trioctahedral true K-rich micas, the average basal O_{bas}-T-O_{bas} angle $\langle\tau\rangle_{bas}$ decreases as Si^{4+} increases relative to Al^{3+} in the tetrahedral sheet. We have illustrated this effect by plotting the average basal edge length $\langle O\text{-}O\rangle_{bas}$ as a function the average basal bond length $\langle T\text{-}O\rangle_{bas}$ actually refined for the 170 trioctahedral-1*M* mica structures (Figure 6.85, Subsection 6.4.3), in comparison with simple geometrical model $\tau_{bas} = constant$ prediction lines (Eqs. 6.15, Subsection 6.2.4). This convenient data representation allows us to conclude that: i) specific O_{bas}-T-O_{bas} angles are preferred for a given tetrahedral composition in trioctahedral-1*M* true micas (as well as O_{api}-T-O_{bas} angles, via Eq. 6.15; see Figure 6.40, Subsection 6.2.4); and ii) an O_{bas}-T-O_{bas} angle of 108.5° is favoured for K-rich micas having an $\langle AlSi_3\rangle$ tetrahedral sheet.

The inner (i.e., shortest first nearest neighbour) interlayer site bond length of a given cationic species monotonously decreases as the tetrahedral rotation α increases (Figures 6.93-6.94, Subsection 6.4.4), as would be expected since the interlayer-cation coordination progressively goes from 12-fold (α=0°) to 6-fold (α=30°) as a function of α [Weiss *et al.* 1992]. The range of average inner interlayer site bond lengths actually observed in natural biotite-1*M* single-crystals goes from 2.85 to 3.15 Å (Figures 6.91 and 6.94, Subsection 6.4.4), whereas the accepted bond lengths for potassium between 6- and 12-fold coordination range from 2.76 to 3.16 Å [Shannon 1976].

Contrary to [Hewitt & Wones 1975], we find that the smaller K-O bonds do not appear to be constrained by the monotonous interlayer site bond length reduction with increasing tetrahedral rotation. The range of K-O bond lengths that we have obtained from the measured *c* lattice parameters of our synthetic powder samples is also consistent with these findings (Figures 6.91 and 6.94, Subsection 6.4.4). The large K-O bond lengths (~3.22 Å) of our synthetic annite (Fe end-member) samples are not unreasonable considering that natural Fe^{2+}-rich micas usually have a significant content of octahedral Al^{3+} [Foster 1960; Redhammer & Roth 2002], which increases α and thus reduces the K-O bonds. Our synthetic annite samples are actually the most Fe^{2+}-rich, $AlSi_3$ micas one can produce [Redhammer *et al.* 1993; Mercier *et al.* 1996, 1999].

To analyse the structural misfit between octahedral and tetrahedral sheets, we have plotted the evolution of the tetrahedral rotation angle α as a function of the ratio of (mean-octahedral-bond-length)/(mean-basal-tetrahedral-bond-length) for both our synthetic powders and the 170 trioctahedral-1*M* single-crystals (Figures 6.86-6.88, Subsection 6.4.3). From this data representation, in comparison with octahedral and tetrahedral constant-flattening-angle prediction lines (explained in Subsection 6.4.4), we have demonstrated that the plateau of *b* lattice parameters measured in the Mg-Ni JLR solid solutions series actually corresponds to an upper limit of tetrahedral rotation angle at $\alpha \cong 9.5°$.

By chemical substitution of a smaller Ni^{2+} for a larger Mg^{2+} in the octahedral sheets at a constant $<AlSi_3>$ tetrahedral composition, one expects the dimensional tetrahedral-to-octahedral sheet misfit to progressively grow so that α becomes larger as the average octahedral bond size is reduced. Given that the behaviour in *b* is real, therefore, this constitutes the first direct experimental evidence of the existence a lower limit of lateral extension concurrent with an upper limit of α-rotation at a given tetrahedral composition.

The distributions of α for the groups of biotite-1*M* single-crystals having different tetrahedral compositions also support the above findings (Figure 6.90, Subsection 6.4.3): i) an upper limit of $\alpha \cong 9.5°$ occurs in trioctahedral-1*M* K-rich samples having an $<AlSi_3>$ tetrahedral sheet; and ii) the upper limit of α-rotation appears to be tetrahedral composition dependent.

We conclude that the tetrahedral-sheet composition is the main controlling factor for both the *O-T-O* angles and the upper limit of tetrahedral rotation α in trioctahedral-1*M* true micas, whereas the monotonous variation of the inner interlayer site bond length of a given cationic species with α does not appear to be a limiting factor in K-rich micas. In trioctahedral-1*M* K-rich micas having an$<AlSi_3>$ tetrahedral sheet, an O_{bas}-*T*-O_{bas} angle of 108.5° is favoured and an upper limit of tetrahedral rotation of $\alpha \cong 9.5°$ is present in both synthetic powder and natural single-

crystal samples. The presence of well defined limiting upper values of α-rotation as a function of tetrahedral compositions at room temperature may explain the Al-substitution limits in synthetic biotite solid solutions.

Chapter 8. Conclusions

The main conclusions and results of this work are as follows.

- Fractional atomic coordinates were derived in terms of the atomic positions in a 1*M* unit cell of space-group type *C*2/*m* for each known homogeneous mica polytype of ideal space-group type ($2M_1$ and $2M_2$, s.g. *C*2/*c*; 2*O*, s.g. *Ccmm* ; 3*T*, s.g. $P3_112$) (Chapter 4). The coordinates ensure that all TOT layers in each stacking polytype structure are the same 1*M*-type TOT layer, and were used to determine stacking polytype contents in our synthetic powder samples (Subsection 5.2).

- The relationship

$$b = \sqrt{3}a$$

that would rigorously follow from hexagonal symmetry of an octahedral sheet is found to hold within experimental error for all synthetic powder samples studied and for the great majority (231 of 235) of natural and synthetic single-crystal samples (having various degrees of geometric meso-octahedral and geometric homo-octahedral character) and including all stacking polytypes (Figures 6.2 and 6.3, Section 6.1).

- The four noted exceptions to the observed $b = \sqrt{3}a$ rule

  Norrishite sample 1*M* No. 80
  Anandite sample 2*O* No. 2
  Dehydroxylated paragonite sample $2M_1$ No. 26
  Lepidolite sample $2M_1$ No. 33

presumably correspond to deviations from in-plane pseudo-hexagonal symmetry induced for example by chemical order (Section 6.1).

- The relation

$$(c/a)\cos\beta^* = 1/3$$

is found to hold exactly (within experimental error) for all (75) synthetic powder samples (indexed assuming 1*M* stacking polytype, space-group type C2/m) whereas it does not hold in general for the (128) natural and (42) synthetic single-crystal trioctahedral-1*M* mica structural refinements of *C*2/*m* symmetry (Figures 6.69-6.72, Subsection 6.3.6). The latter relation is predicted to hold for geometric homo-octahedral sheets (having equal *M*1 and *M*2 site bond lengths; Subsection 6.2.2) and not to hold for geometric meso-octahedral sheets (having unequal *M*1 and *M*2 site bond lengths; Subsection 6.2.3) (Figure 6.61-6.62, Subsection 6.3.5; Section 7.2).

- Certain in-plane intra-layer displacements within a TOT layer between atoms located above and below the octahedral-cation plane are predominantly a direct consequence of the geometric meso-octahedral character of the octahedral sheets in trioctahedral-1*M* single-crystals (Figures 6.63-6.67, Subsection 6.3.5; Section 7.2).

- All trioctahedral-1*M* mica structural refinements that follow the $b = \sqrt{3}a$ rule have octahedral counter-rotation angles δ_{M2} that exactly (within experimental error) follow the geometric meso-octahedral sheet model, which, assuming only a uniform octahedral thickness and site-specific *M*1 and *M*2 bond lengths, predicts site-specific flattening angles and a counter-rotation angle for the *M*2 site, δ_{M2}, that is uniquely determined by the bond length difference between the *M*1 and *M*2 sites (Subsection 6.2.3; Eqs. 6.37-6.38, Figure 6.32, Subsection 6.3.2; Section 7.3).

- The exact agreement (within experimental error) of the geometric meso-octahedral sheet model with observations in trioctahedral-1*M* micas of *C*2/*m* symmetry (Eqs. 6.37, Figure 6.32, Subsection 6.3.2) permits the identification of two key parameters to quantify or predict the effects of different octahedral *M*1/*M*2 chemical (cationic) ordering patterns in these structures (Section 7.3): i) the normalized squared octahedral size difference, $[\langle M1\text{-}O\rangle^2 - \langle M2\text{-}O\rangle^2]/a^2$, and ii) the counter-rotation angle of the M2 site, δ_{M2}.

- Plots of lattice parameter *b* as a function the mean octahedral cation-anion bond length are particularly instructive and allow the following distinction to be made. Unoxidized synthetic divalent solid solution series (between Mg^{2+}, Ni^{2+}, Co^{2+}, and Fe^{2+}) tend to evolve along constant flattening angle lines as the mean octahedral bond length increases, whereas trivalent octahedral cation (Fe^{3+} and Al^{3+}) and vacancy bearing synthetic solid solution series and natural biotite-1*M* single-crystals follow trends with decreasing flattening angles as the average bond length of the octahedral sheet increases (Figure 6.76-6.78, Subsection 6.4.2; Section 7.3).

- The average octahedral flattening angle of trioctahedral-1*M* micas of *C*2/*m* symmetry is determined by both the octahedral cationic composition and the tetrahedral-to-octahedral sheet mismatch, whereas differences in flattening angles of *M*1 and *M*2 sites depend on the degrees of octahedral *M*1/*M*2 chemical ordering which occur (Section 7.3).

- Flat tetrahedral sheets having tetrahedral apical bonds perpendicular to the *ab*-plane are only possible in 2:1 layer silicates having geometric homo-octahedral sheets. Because of unavoidable structural constraints, a tetrahedral sheet comprised of coplanar equilateral triangular basal faces cannot be arranged to match a geometric meso-octahedral sheet. For a 1*M* structure of *C*2/*m* symmetry, a straightforward means to accommodate a geometric meso-octahedral sheet is to have basal-oxygen plane corrugation. (Figure 6.45, Subsection 6.3.3; Section 7.4)

- The predicted tetrahedral sheet corrugation is seen to be in direct response to the difference in *M*1 and *M*2 bond lengths (Figure 6.44, Subsection 6.3.3) and corresponds to lowering (*M*1 > *M*2) or raising (*M*1 < *M*2) of O1 atoms relative to (O2-O2') basal edges (Figure 6.45, Subsection 6.3.3; Section 7.4).

- Tetrahedral corrugation cannot simply be accomplished by cooperative tilting of tetrahedrons having a 'regular' geometrical shape, as the tetrahedrons themselves *must* be distorted in the process such as to have isosceles or scalene basal-oxygen triangular faces and unequal basal bond lengths arising from unavoidable structural constraints (Figure 6.45, Subsection 6.3.3; Section 7.4).

- The inner (i.e., shortest first near neighbour) interlayer site bond length of a given interlayer cation species monotonously increases as the tetrahedral rotation angle α decreases in trioctahedral-1*M* micas, for both synthetic powders and natural single-crystals (Figures 6.93 and 6.94, Subsection 6.4.4; Section 7.5).

- Specific *O-T-O* angles are preferred for a given tetrahedral sheet composition in trioctahedral-1*M* true micas (Figure 6.40, Subsection 6.3.3; Figure 6.85, Subsection 6.4.3; Section 7.5). For K-rich micas having an $<AlSi_3>$ tetrahedral composition, an O_{bas}-T-O_{bas} angle of 108.5° is favoured and an upper limit of tetrahedral rotation of $\alpha \approx 9.5°$ is present, for both synthetic powders and natural single-crystal samples (Subsection 6.4.3; Section 7.5).

- Other attempts at applying geometric crystal chemical models and at identifying structuro-chemical relationships from structural refinement data will benefit from the perspective of our more complete and systematic approach based on pursuing simple geometrical models using 'regular' coordination polyhedrons and characteristic cation-specific bond lengths up to the limit beyond which such models are shown to necessarily breakdown because of unavoidable 'non-regular' polyhedral distortions.

Appendix N. Impurity reflections for the annite-oxyannite-ferrioxyannite series

The impurity reflections observed in the diffractograms of these samples are reported in [Rancourt *et al.* 2001].

Appendix O. Mössbauer fitting parameters for RT thickness corrected spectra

Appendix U. Maple worksheets used for stacking polytype derivation

Stacking polytype 2*M*1 derivation

Let us first write the fractional atomic coordinates in the *Standard C2/m* 1-layer unit-cell.

The interlayer cations (K) are at the following positions within the C 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry (1/2,1/2,0)+

2 *b* 2/*m* (0,1/2,0)

```
> with(linalg): K[1] := [0,1/2,1]; K[2]:= [1/2,0,1];K[3]:= [1/2,0,0];K[4]:= [0,1/2,0];
Warning, new definition for norm
Warning, new definition for trace
```

$$K_1 := \left[0, \frac{1}{2}, 1\right]$$

$$K_2 := \left[\frac{1}{2}, 0, 1\right]$$

$$K_3 := \left[\frac{1}{2}, 0, 0\right]$$

$$K_4 := \left[0, \frac{1}{2}, 0\right]$$

The M1 cations are at the following positions within the *C* 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

2 *c* 2/*m* (0,0,1/2)

```
> M1[1] := [0,0,1/2]; M1[2]:= evalm(M1[1]+[1/2,1/2,0]);M1[3] := [3/2,1/2,1/2];
```

$$M1_1 := \left[0, 0, \frac{1}{2}\right]$$

$$M1_2 := \left[\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right]$$

$$M1_3 := \left[\frac{3}{2}, \frac{1}{2}, \frac{1}{2}\right]$$

The M2 cations are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *h* 2 (1) 0 , y ,1/2 (2) 0, -y , 1/2

```
> M2[1] := [0,M2y,1/2]; M2[2]:= [M2[1][1],-M2[1][2]+1,M2[1][3]];
  M2[3]:=evalm(M2[1]+[1/2,1/2,0]);M2[4]:=evalm(M2[2]+[1/2,-1/2,0]);
  M2[5]:=[1,M2[1][2],1/2];M2[6]:=[M2[1][1]+1,-M2[1][2],1/2];
```

$$M2_1 := \left[0, M2y, \frac{1}{2}\right]$$

$$M2_2 := \left[0, -M2y + 1, \frac{1}{2}\right]$$

$$M2_3 := \left[\frac{1}{2}, \frac{1}{2} + M2y, \frac{1}{2}\right]$$

$$M2_4 := \left[\frac{1}{2}, \frac{1}{2} - M2y, \frac{1}{2}\right]$$

$$M2_5 := \left[1,\ M2y,\ \frac{1}{2}\right]$$

$$M2_6 := \left[1,\ -M2y,\ \frac{1}{2}\right]$$

The O4 oxygen atoms are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *i* *m* (1) x , 0 , z
(2) -x , 0 , -z
(3) 1/2 + x , 1/2 , z
(4) 1/2 - x , 1/2 , -z

```
> O4[1]:=[O4x,1/2,O4z];  O4[2]:= [-O4[1][1]+1,O4[1][2],-O4[1][3]+1];
  O4[3]:=[O4[1][1]+1/2,O4[1][2]-1/2,O4[1][3]];
  O4[4]:=[-O4[1][1]+1/2,O4[1][2]-1/2,-O4[1][3]+1];
```

$$O4_1 := \left[O4x,\ \frac{1}{2},\ O4z\right]$$

$$O4_2 := \left[-O4x + 1,\ \frac{1}{2},\ -O4z + 1\right]$$

$$O4_3 := \left[O4x + \frac{1}{2},\ 0,\ O4z\right]$$

$$O4_4 := \left[-O4x + \frac{1}{2},\ 0,\ -O4z + 1\right]$$

The O3 oxygen atoms are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

8 *j* 1 (1) x , y , z
(2) -x , y , -z
(3) -x , - y , - z
(4) x , -y , z
(5) 1/2 + x , 1/2 + y , z
(6) 1/2 - x , 1/2 + y , -z
(7) 1/2 - x , 1/2 - y , -z
(8) 1/2 + x , 1/2 - y , z

```
> O3[1]:=[O3x,O3y,O3z];  O3[2]:= [-O3[1][1]+1,O3[1][2],-O3[1][3]+1];
  O3[3]:=[-O3[1][1]+1,-O3[1][2]+1,-O3[1][3]+1];
  O3[4]:=[O3[1][1],-O3[1][2]+1,O3[1][3]];
  O3[5]:=[O3[1][1]+1/2,O3[1][2]+1/2,O3[1][3]];
  O3[6]:=[1/2-O3[1][1],1/2+O3[1][2],-O3[1][3]+1];
  O3[7]:=[1/2-O3[1][1],1/2-O3[1][2],-O3[1][3]+1];
  O3[8]:=[1/2+O3[1][1],1/2-O3[1][2],O3[1][3]];
```

$$O3_1 := [O3x,\ O3y,\ O3z]$$

$$O3_2 := [-O3x + 1,\ O3y,\ -O3z + 1]$$

$$O3_3 := [-O3x + 1,\ -O3y + 1,\ -O3z + 1]$$

$$O3_4 := [O3x,\ -O3y + 1,\ O3z]$$

$$O3_5 := \left[O3x + \frac{1}{2},\ O3y + \frac{1}{2},\ O3z\right]$$

$$O3_6 := \left[\frac{1}{2} - O3x,\ O3y + \frac{1}{2},\ -O3z + 1\right]$$

$$O3_7 := \left[\frac{1}{2} - O3x, \frac{1}{2} - O3y, -O3z + 1\right]$$

$$O3_8 := \left[O3x + \frac{1}{2}, \frac{1}{2} - O3y, O3z\right]$$

The T cations are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

8 *j* 1 (1) x , y , z
(2) -x , y , -z
(3) -x , - y , - z
(4) x , -y , z
(5) 1/2 + x , 1/2 + y , z
(6) 1/2 - x , 1/2 + y , -z
(7) 1/2 - x , 1/2 - y , -z
(8) 1/2 + x , 1/2 - y , z

```
> T[1]:=[Tx,Ty,Tz];  T[2]:= [-T[1][1]+1,T[1][2],-T[1][3]+1];

Stacking polytype 2*M*2 derivation

Let us first write the fractional atomic coordinates in the *Standard C2/m* 1-layer unit-cell.

The interlayer cations (K) are at the following positions within the *C* 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry (1/2,1/2,0)+

2 *b* 2/*m* (0,1/2,0)

```
> with(linalg): K[1] := [0,1/2,0]; K[2]:= [-1/2,0,0]; K[3]:= [1/2,0,1]; K[4]:= [1/2,0,0];
Warning, new definition for norm
Warning, new definition for trace
```

$$K_1 := \left[0, \frac{1}{2}, 0\right]$$

$$K_2 := \left[\frac{-1}{2}, 0, 0\right]$$

$$K_3 := \left[\frac{1}{2}, 0, 1\right]$$

$$K_4 := \left[\frac{1}{2}, 0, 0\right]$$

The M1 cations are at the following positions within the *C* 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

2 *c* 2/*m* (0,0,1/2)

```
> M1[1] := [0,0,1/2]; M1[2]:= evalm(M1[1]+[1/2,1/2,0]);M1[3] := [3/2,1/2,1/2];
```

$$M1_1 := \left[0, 0, \frac{1}{2}\right]$$

$$M1_2 := \left[\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right]$$

$$M1_3 := \left[\frac{3}{2}, \frac{1}{2}, \frac{1}{2}\right]$$

The M2 cations are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *h* 2 (1) 0 , y ,1/2 (2) 0, -y , 1/2

```
> M2[1] := [0,M2y,1/2]; M2[2]:= [M2[1][1],-M2[1][2],M2[1][3]];
  M2[3]:=evalm(M2[1]+[1/2,1/2,0]);M2[4]:=evalm(M2[2]+[1/2,1/2,0]);
  M2[5]:=[0,M2[1][2],1/2];M2[6]:=[M2[1][1],-M2[1][2]+1,1/2];
```

$$M2_1 := \left[0, M2y, \frac{1}{2}\right]$$

$$M2_2 := \left[0, -M2y, \frac{1}{2}\right]$$

$$M2_3 := \left[\frac{1}{2}, \frac{1}{2} + M2y, \frac{1}{2}\right]$$

$$M2_4 := \left[\frac{1}{2}, \frac{1}{2} - M2y, \frac{1}{2}\right]$$

$$M2_5 := \left[0,\ M2y,\ \frac{1}{2}\right]$$

$$M2_6 := \left[0,\ -M2y + 1,\ \frac{1}{2}\right]$$

The O4 oxygen atoms are at the following positions within the $C\ 1\ 2/m\ 1$ space group (s.g. No. 12; unique axis b):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *i* *m* (1) x , 0 , z
(2) -x , 0 , -z
(3) 1/2 + x , 1/2 , z
(4) 1/2 - x , 1/2 , -z

```
> O4[1]:=[O4x,1/2,O4z];  O4[2]:= [-O4[1][1]+1,O4[1][2],-O4[1][3]+1];
  O4[3]:=[O4[1][1]+1/2,O4[1][2]+1/2-1,O4[1][3]];
  O4[4]:=[-O4[1][1]+1/2,O4[1][2]+1/2-1,-O4[1][3]+1];
```

$$O4_1 := \left[O4x,\ \frac{1}{2},\ O4z\right]$$

$$O4_2 := \left[-O4x + 1,\ \frac{1}{2},\ -O4z + 1\right]$$

Stacking polytype 2O derivation

Let us first write the fractional atomic coordinates in the *Standard C2/m* 1-layer unit-cell.

The interlayer cations (K) are at the following positions within the C 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry (1/2,1/2,0)+

2 *b* 2/*m* (0,1/2,0)

```
> with(linalg): K[1] := [0,1/2,0]; K[2]:= [1/2,0,0];
Warning, new definition for norm
Warning, new definition for trace
```

$$K_1 := \left[0, \frac{1}{2}, 0\right]$$

$$K_2 := \left[\frac{1}{2}, 0, 0\right]$$

The M1 cations are at the following positions within the *C* 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

2 *c* 2/*m* (0,0,1/2)

```
> M1[1] := [0,0,1/2]; M1[2]:= evalm(M1[1]+[1/2,1/2,0]);
```

$$M1_1 := \left[0, 0, \frac{1}{2}\right]$$

$$M1_2 := \left[\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right]$$

The M2 cations are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *h* 2 (1) 0 , y ,1/2 (2) 0, -y , 1/2

```
> M2[1] := [0,M2y,1/2]; M2[2]:= [M2[1][1],-M2[1][2]+1,M2[1][3]];
  M2[3]:=evalm(M2[1]+[1/2,1/2,0]); M2[4]:=evalm(M2[2]+[1/2,-1/2,0]);
```

$$M2_1 := \left[0, M2y, \frac{1}{2}\right]$$

$$M2_2 := \left[0, -M2y + 1, \frac{1}{2}\right]$$

$$M2_3 := \left[\frac{1}{2}, \frac{1}{2} + M2y, \frac{1}{2}\right]$$

$$M2_4 := \left[\frac{1}{2}, \frac{1}{2} - M2y, \frac{1}{2}\right]$$

The O4 oxygen atoms are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *i* *m* (1) x , 0 , z
(2) -x , 0 , -z
(3) 1/2 + x , 1/2 , z

(4) 1/2 - x , 1/2 , -z

```
> O4[1]:=[O4x,1/2,O4z];  O4[2]:= [-O4[1][1]+1,O4[1][2],-O4[1][3]+1];
  O4[3]:=[O4[1][1]+1/2,O4[1][2]-1/2,O4[1][3]];
  O4[4]:=[-O4[1][1]+1/2,O4[1][2]-1/2,-O4[1][3]+1];
```

$$O4_1 := \left[O4x, \frac{1}{2}, O4z \right]$$

$$O4_2 := \left[-O4x + 1, \frac{1}{2}, -O4z + 1 \right]$$

$$O4_3 := \left[O4x + \frac{1}{2}, 0, O4z \right]$$

$$O4_4 := \left[-O4x + \frac{1}{2}, 0, -O4z + 1 \right]$$

The O3 oxygen atoms are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

8 *j* 1 (1) x , y , z
(2) -x , y , -z
(3) -x , - y , - z
(4) x , -y , z
(5) 1/2 + x , 1/2 + y , z
(6) 1/2 - x , 1/2 + y , -z
(7) 1/2 - x , 1/2 - y , -z
(8) 1/2 + x , 1/2 - y , z

```
> O3[1]:=[O3x,O3y,O3z];  O3[2]:= [-O3[1][1]+1,O3[1][2],-O3[1][3]+1];
  O3[3]:=[-O3[1][1]+1,-O3[1][2]+1,-O3[1][3]+1];
  O3[4]:=[O3[1][1],-O3[1][2]+1,O3[1][3]];
  O3[5]:=[O3[1][1]+1/2,O3[1][2]+1/2,O3[1][3]];
  O3[6]:=[1/2-O3[1][1],1/2+O3[1][2],-O3[1][3]+1];
  O3[7]:=[1/2-O3[1][1],1/2-O3[1][2],-O3[1][3]+1];
  O3[8]:=[1/2+O3[1][1],1/2-O3[1][2],O3[1][3]];
```

$$O3_1 := [O3x, O3y, O3z]$$

$$O3_2 := [-O3x + 1, O3y, -O3z + 1]$$

$$O3_3 := [-O3x + 1, -O3y + 1, -O3z + 1]$$

$$O3_4 := [O3x, -O3y + 1, O3z]$$

$$O3_5 := \left[O3x + \frac{1}{2}, O3y + \frac{1}{2}, O3z \right]$$

$$O3_6 := \left[\frac{1}{2} - O3x, O3y + \frac{1}{2}, -O3z + 1 \right]$$

$$O3_7 := \left[\frac{1}{2} - O3x, \frac{1}{2} - O3y, -O3z + 1 \right]$$

$$O3_8 := \left[O3x + \frac{1}{2}, \frac{1}{2} - O3y, O3z \right]$$

The T cations are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

8 *j* 1 (1) x , y , z
(2) -x , y , -z
(3) -x , - y , - z

Stacking polytype 3*T* derivation

Let us first write the fractional atomic coordinates in the *Standard C2/m* 1-layer unit-cell.

The interlayer cations (K) are at the following positions within the C 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry (1/2,1/2,0)+

2 *b* 2/*m* (0,1/2,0)

```
> with(linalg): K[1] := [0,1/2,1]; K[2]:= [-1/2,0,1];K[3]:= [1/2,0,1];K[4]:= [1/2,0,0];
Warning, new definition for norm
Warning, new definition for trace
```

$$K_1 := \left[0, \frac{1}{2}, 1\right]$$

$$K_2 := \left[\frac{-1}{2}, 0, 1\right]$$

$$K_3 := \left[\frac{1}{2}, 0, 1\right]$$

$$K_4 := \left[\frac{1}{2}, 0, 0\right]$$

The M1 cations are at the following positions within the *C* 1 2/*m* 1 space group (sg No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

2 *c* 2/*m* (0,0,1/2)

```
> M1[1] := [0,0,1/2]; M1[2]:= evalm(M1[1]+[1/2,1/2,0]);M1[3] := [3/2,1/2,1/2];
```

$$Ml_1 := \left[0, 0, \frac{1}{2}\right]$$

$$Ml_2 := \left[\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right]$$

$$Ml_3 := \left[\frac{3}{2}, \frac{1}{2}, \frac{1}{2}\right]$$

The M2 cations are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *h* 2 (1) 0 , y ,1/2 (2) 0, -y , 1/2

```
> M2[1] := [0,yM2,1/2]; M2[2]:= [M2[1][1],-M2[1][2]+1,M2[1][3]];
  M2[3]:=evalm(M2[1]+[1/2,1/2,0]);M2[4]:=evalm(M2[2]+[1/2,-1/2,0]);M2[5]:=[0,0,0]:M2[6]:=[0
  ,0,0]:
```

$$M2_1 := \left[0, yM2, \frac{1}{2}\right]$$

$$M2_2 := \left[0, -yM2 + 1, \frac{1}{2}\right]$$

$$M2_3 := \left[\frac{1}{2}, \frac{1}{2} + yM2, \frac{1}{2}\right]$$

$$M2_4 := \left[\frac{1}{2}, \frac{1}{2} - yM2, \frac{1}{2}\right]$$

The O4 oxygen atoms are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

4 *i* *m* (1) x , 0 , z
(2) -x , 0 , -z
(3) 1/2 + x , 1/2 , z
(4) 1/2 - x , 1/2 , -z

```

The O2 oxygen atoms are at the following positions within the C 1 2/*m* 1 space group (s.g. No. 12; unique axis *b*):

Multplicity, Wyckoff letter, Site symmetry, Coordinates (1/2,1/2,0)+

8	*j*	1	(1)	x	y	z
			(2)	-x	y	-z
			(3)	-x	-y	-z
			(4)	x	-y	z
			(5)	1/2 + x	1/2 + y	z
			(6)	1/2 - x	1/2 + y	-z
			(7)	1/2 - x	1/2 - y	-z
			(8)	1/2 + x	1/2 - y	z

Table V.1. Continued.

Diffractograms considered	Specimen Characteristics	Visual		FP fitting	
		$(\sigma_j)_{av}$ [a]	$(\sigma_j)_{sd}$ [a]	$(\sigma_j)_{av}$ [a]	$(\sigma_j)_{sd}$ [a]
149-150-151-152-153	same IKO-Ann smear, left goniometer, repeated measurements under various experimental configurations	0.0128	0.0058	0.0078	0.0049
135-137-139	smears of different size-fractions of IKO-Ann, right goniometer, same experimental configuration	0.0138	0.0066	0.0050	0.0060
136-138	smears of different size-fractions of IKO-Ann, left goniometer, same experimental configuration	0.0130	0.0084	0.0129	0.0047
145-148-154-6NOV[b]	various smears of SRMs, left goniometer, various experimental configurations	0.0048	0.0019	0.0052	0.0030
140-165	right goniometer, different smears of SRMs, different experimental configurations	0.0033	0.0020	0.0021	0.0013

[a] These values are expressed in °2θ and are computed excluding individual σ_j values greater than 0.03 °2θ.

[b] 6NOV refers to the series of diffractograms SRM640c_6NOV2001.

Table V.2. Comparison of $(\sigma_j)_{av}$ and $(\sigma_j)_{sd}$ values computed using individual $K\alpha_1$ line positions evaluated by the visual estimation and the FP line-profile fitting methods (Table V.1) for various sets of diffractograms of a given sample.

[1] UC Vol.: unit cell volume.

[2] $N_{refl.}$: number of reflections used in the refinement.

[3] N_{hkl}: number of *hkl* values successfully assigned in the refinement.

[4] W = all size fractions; S = small size fraction, d < 1 μm; L = large size fraction, d > 1 μm (see [Rancourt *et al*. 2001]).

[5] Powder pattern meaured using a Gandolfi camera that used CoKα radiation (λ = 1.7902 Å assumed in the refinement).
