SUMMARY

To investigate the role(s) of the globular domain (residues 1-43) and the first class A helix (residues 44-65) of apolipoprotein A-I (apoA-I) in the metabolism of high density lipoproteins (HDL), we have taken a combined *in vitro* and *in vivo* approach. This work demonstrates that both the globular domain and helix 1 of apoA-I are important for the maturation of HDL. Deletions of these domains were associated with progressive impairments in the ability of apoA-I to activate lecithin:cholesterol acyltransferase (LCAT) and form cholesteryl ester rich HDL. While phospholipid binding was significantly reduced for both apoA-I mutants relative to wild-type apoA-I, cholesterol efflux was not affected by these deletions. We propose both the globular domain and helix 1 are critical LCAT activating domains of apoA-I and are required for the maturation of HDL *in vivo*.

DEDICATION

I dedicate my thesis to my family and friends whose constant support made this work possible. James Richard Scott, Lynda Scott, Barry Scott and Colleen Sweet have provided a guiding light and encouragement without which my efforts would have been fruitless. Furthermore, I dedicate this work to my grandparents Stanley and Jean Joynt and Grace Scott whose “joie de vie” is an inspiration to us all.

“Our doubts are traitors,
And make us lose the good we oft might win
By fearing to attempt.”

William Shakespeare (Measure by Measure)

ACKNOWLEDGEMENTS

I would like to thank my supervisor and teacher Dr. Yves Marcel for his guidance, support and encouragement and Dan McManus who has provided invaluable tutelage and friendship. The expert assistance and timely advise of Vivian Franklin made my work more efficient and enjoyable. I would also like to acknowledge Dr. James Burgess for his expert academic and technical suggestions. Other members of the Lipoprotein and Atherosclerosis Group at the University of Ottawa Heart Institute made significant contributions to this work, including Andrea MacKenzie, Dr. Robert Scott Kiss, Dr. Phillippe Frank, Susha Zachariah and Cheryl Dollard. Furthermore, I would like to thank Dr. Daniel Sparks, Tracey Neville, Dr. Khai Tran and Jelena Vukmirica for their contributions, as well. Finally, I would like to acknowledge the remaining members of my thesis advisory committee, Dr. Ross Milne and Dr. James Van Huysse.

CHAPTER 1: INTRODUCTION

1.1 Pathogenesis of Atherosclerosis

In 1973, Ross and Glomset proposed the 'Response to Injury Hypothesis' to describe the pathogenesis of the atherosclerotic lesion (1). In this model, oxidatively modified low density lipoproteins (LDL) are retained within the intimal layer of the artery where they elicit complex immune responses causing the recruitment of macrophages and smooth muscle cells from the bloodstream and media, respectively. Subsequent accumulation of extracellular lipid, fibrous elements and a calcium-phosphate matrix are hallmarks of an advanced atheroma that penetrates the arterial lumen restricting blood flow. Thrombosis is highly associated with the rupture of such lesions, occlusion of the arterial lumen and clinical presentation of the disease.

LDL, the major cholesterol containing lipoprotein in the blood, passively diffuses from the circulation to the intima in all areas of all healthy arteries. However, regions of specific arteries prone to atherosclerosis, predominantly areas of arterial branching or curvature, exhibit enhanced retention of LDL via direct interaction between apoB and extracellular matrix proteoglycans (2,3). Limited oxidation of LDL then occurs as reactive oxygen species (ROS), derived from vascular cells, modify the phospholipid component of LDL (4). Oxidized LDL is constitutively endocytosed via interaction with the macrophage scavenger receptors, SR-AI/II and CD36. This process is critical to lipid accumulation within the atherosclerotic lesion as mice lacking either receptor exhibit significantly less atherosclerosis (5,6). Constitutive endocytosis of oxidized LDL induces the formation of large intracellular cholesterol droplets and are consequently referred to as foam cells. Foam cells are the hallmark of the early atherogenic lesion and are responsible for the continual accumulation of cholesterol throughout lesion development.

Inflammatory cytokines secreted from both macrophage and T cells stimulate the proliferation and migration of smooth muscle cells (SMC) from the media to the intima. SMC secrete an extracellular matrix that provides structural support and a fibrous cap to a growing mass of extracellular lipid derived from the death of macrophage foam cells termed the 'necrotic core'. The necrotic core contains, in addition to cholesterol and cell debris, a varying degree of calcification. At this point the lesion size increases first in the direction of the adventitia until a critical point at which the fibrous plaque expands into the arterial lumen restricting blood flow. This thickening of the atherosclerotic plaque contributes to arterial stenosis that further alters arterial hemostasis.

However, thrombosis is highly associated with plaque instability rather than the degree of arterial stenosis. Plaque instability stems from breakdown of the SMC derived extracellular matrix by several well-characterized enzymes secreted from macrophages, including interstitial collagenase, gelatinases, stromolysin and the cathepsins (7). Furthermore, T cells produce IFN- γ that inhibits SMC matrix production. Subsequent to destabilization, plaques can fissure exposing tissue factor to the necrotic core making these sites for platelet attachment. Thrombi of significant size can occlude blood flow in a coronary artery causing unstable angina and myocardial infarction.

1.2 Human Plasma Lipoproteins: General Physical Properties

This section describes the lipid and apolipoprotein composition of the plasma lipoproteins. The information presented here was compiled from previously published review papers and book chapters (8,9). Lipoproteins are microemulsions consisting of a core of neutral lipid, predominantly cholesteryl ester (CE) and triacylglycerol (TG),

surrounded by a phospholipid (PL) monolayer also containing free cholesterol (FC) (Fig. 1-1). All surface lipids are amphipathic and are oriented with their hydrophobic moiety directed towards the lipoprotein core and hydrophilic moiety exposed to the aqueous environment. The apolipoproteins are also amphipathic and situate within the PL monolayer such that hydrophobic domains interact with surface lipid and stabilize the lipoprotein structure while polar residues are exposed to the aqueous environment. The plasma lipoproteins contain exchangeable (apoA-I, apoA-IV, apoC-I, apoC-II, apoC-III and apoE) and/or non-exchangeable (apoB-48 and apoB-100) apolipoproteins. While apoA-II is normally considered an exchangeable apolipoprotein, it remains to be determined how this apolipoprotein is secreted and associated with lipoproteins. Exchangeable apolipoproteins are water soluble in the absence of lipids while non-exchangeable apolipoproteins are insoluble. Thus, *in vivo*, exchangeable apolipoproteins are able to dissociate from one lipoprotein particle and reassociate with another via a lipid-free intermediate. Non-exchangeable apolipoproteins are secreted in the context of a mature lipoprotein particle and remain associated with the lipid moiety until eventual catabolism.

Heterogeneous in size, density and lipid and protein composition (Table 1-1 and 1-2), the plasma lipoproteins are divided into 5 classes and are involved in 3 distinct routes of cholesterol transport. Chylomicrons are the largest lipoprotein particles. Their molecular mass is on the range of 400 MDa and approximately 75-1200 nm in diameter. These lipoproteins are secreted from intestinal enterocytes and transport dietary triacylglycerol to sites of storage and utilization in the body. Due to the lipoprotein size and triacylglycerol content, these are the most buoyant lipoprotein species equilibrating at a density of 0.930 g/mL. The hepatic analogues of chylomicrons are the very low density lipoproteins (VLDL). VLDL are 10-80 MDa particles, range in diameter from 30-80 nm and are slightly

denser than chylomicrons (0.930-1.006 g/mL). These lipoproteins transport TG and cholesterol from the liver to sites of utilization and storage in the body. Hydrolysis of the VLDL TG core generates a smaller and denser lipoprotein particle named intermediate

Figure 1-1: Model of a Spherical Lipoprotein

Lipoproteins are microemulsions assembled such that amphipathic lipid molecules form the surface monolayer while neutral lipids partition to the core and are excluded from the aqueous environment. Apolipoproteins contain amphipathic α -helices and interact with the lipoprotein surface to stabilize the overall structure and mediate interactions with cell surface receptors, lipolytic enzymes and lipid transfer proteins.

density lipoprotein (IDL). IDL are 5-10 MDa lipoproteins, are 25-35 nm in diameter and occupy a density of 1.006-1.019 g/mL. This lipoprotein class is intermediate in density between VLDL and the subsequent lipoprotein class, the low density lipoprotein (LDL). LDL are generated by the hydrolysis of IDL and, as such, are derived from VLDL initially secreted from the liver. These lipoproteins are approximately 2.3 MDa in size, 18-25 nm in diameter and equilibrate at a density of 1.019-1.063 g/mL. Finally, high density lipoproteins (HDL) are composed of two principal subclasses, HDL₂ and HDL₃. HDL are not assembled intracellularly and secreted as are chylomicrons and VLDL or derived from the

catabolism of precursors like IDL and LDL. HDL are assembled within the circulation from exchangeable apolipoprotein and lipid constituents. HDL also differ from other lipoprotein classes in that they transport lipid in the opposite direction as compared to the

apoB-100 containing lipoproteins, transporting excess lipid from peripheral tissues to the liver for biliary secretion and recycling. Furthermore, HDL cholesterol levels are inversely correlated with the risk of coronary artery disease as established in clinical studies.

1.3 HDL Metabolism

High density lipoproteins (HDL) are the smallest and most dense lipoprotein class and transport cholesterol from extra-hepatic cells to the liver for excretion in the bile and recycling, a process referred to as Reverse Cholesterol Transport (10). This pathway is widely accepted as the primary mechanism by which HDL exert their anti-atherogenic effects. This section is devoted to the description and interconversion of HDL subclasses, individual steps in the reverse cholesterol transport pathway and HDL catabolism.

1.3.1 Introduction to HDL Structure

This summary of HDL structure was compiled from previously published review articles (refer to refs (11,12) for a more detailed description). Plasma HDL particles range in diameter from 5-12 nm with molecular masses of 200-400 kDa. The organization of the lipid constituents in HDL is similar to other plasma lipoproteins and was illustrated in Fig. 1-1, spherical microemulsions assembled such that apolipoproteins and FC situate within the PL monolayer while neutral lipids, CE and TG, partition to the HDL core.

Due to the significantly smaller size of HDL, special consideration must be made to the relative contribution of core versus surface constituents as small lipoproteins have a greater surface area to volume ratio. The lipoprotein surface monolayer is 20 Å thick and accounts for a significant proportion of the lipid content and approximately 80-85% of the HDL particle volume. While chylomicron and VLDL mass is predominantly TG, 80% of

HDL mass is apolipoprotein and PL. The predominant apolipoprotein constituent of HDL is apoA-I, which accounts for approximately 70% of the protein mass while apoA-II and the apoCs constitute 20% and 10%, respectively.

HDL are perhaps the most underrated lipoprotein class due to the manner in which the plasma values are expressed. HDL plasma concentrations are expressed in terms of HDL cholesterol values as are LDL, the predominant cholesterol carrying lipoprotein particle in the plasma. However, HDL and LDL levels in plasma are similar with respect to total mass (lipid + protein) and, if HDL particle size is taken into account, plasma HDL particle concentration is 10-20 fold greater.

1.3.2 Identification of HDL Subclasses

The formation of HDL precursors and their subsequent conversion to spherical, CE-rich lipoproteins is referred to as HDL maturation. HDL are very heterogeneous in size, density, lipid and apolipoprotein content. The following considers individual HDL subclasses differing in these physical properties, their respective roles in HDL metabolism and reverse cholesterol transport.

1.3.2.1 HDL₁ / HDL₂ / HDL₃

Gofman and coworkers separated plasma HDL into three distinct pools by both non-denaturing gradient gel electrophoresis and density ultracentrifugation, which are referred to as HDL₁, HDL₂ and HDL₃ in an order of increasing density and decreasing size (13). Of these, HDL₂ and HDL₃ are by far the most abundant in normolipidemic humans. HDL₂ are 360 kDa in size, 9-12 nm in diameter and occupy a density of 1.063-1.125 g/mL. HDL₃ occupy a density ranging from 1.125-1.210 g/mL, are approximately 175 kDa in size

and 5-9 nm in diameter. The core volume of HDL₂ is 3.5-fold greater than HDL₃ while the increase in protein content is only 50%. The mass difference in protein content may correspond to the addition of one molecule of apoA-I (14) however this has not been demonstrated.

Figure 1-2: HDL Subclasses as Defined by Their Physical Properties and Separation Procedures

Adapted from Barrans *et al.* (15)

Interindividual variations in HDL concentrations are due predominantly to changes in HDL₂ but not HDL₃ levels. This may be related to LPL activity, which is in general proportional to HDL₂ levels (16-18). HDL₃ readily accept PL, FC and apolipoproteins from lipolyzed VLDL and cell membranes to generate an intermediate HDL₂ particle, referred to as HDL_{2a}. This step alone is insufficient for the formation of true HDL₂, referred to as HDL_{2b}, which requires the additional enrichment of LCAT-derived CE. Therefore, the conversion of HDL₃ to HDL_{2b} is thought to constitute a two-step process. The first step involves the transfer of LPL- and cell-derived surface components to HDL₃, and may be

reversible, while enrichment with CE mediated by LCAT is necessary for the ultimate conversion to HDL₂.

HDL₁ is an important lipoprotein constituent in rodents (19-21) and is present, but not abundant, in human plasma (22). This HDL subclass is larger than HDL₂ (13-14 nm in diameter) and differs significantly from HDL_{2,3} as apoE accounts for an estimated 60% of the total protein content (21). These lipoproteins form in plasma, apparently from HDL₂, and represent a further progression in HDL maturation. Incubation of human plasma in the test tube at 37°C results in a pronounced increase in HDL₁ levels, presumably due to the accumulation of LCAT-derived CE in HDL (23). Thus, it appears that the conversion of HDL₂ to HDL₁ is governed by the same reactions that are responsible for the transformation of HDL₃ to HDL₂. The emergence of HDL₁-like particles in cholesterol-fed animals suggests that native HDL₁ form in response to the need to transport larger quantities of HDL cholesterol than are normally required (24). The replacement of apoA-I with apoE may result from the poor association of apoA-I with larger lipoprotein particles and the size of HDL₁ may represent the limit at which apoA-I is thermodynamically the favoured HDL protein constituent.

1.3.2.2 Pre β - and α -HDL

On the basis of their electrophoretic mobility in agarose, HDL are divided into those with α - and pre β - mobility describing their migration relative to α and β globulins and are referred to as α - and pre β -HDL (25,26). This technique separates plasma lipoproteins by surface charge, which is determined by both lipid and apolipoprotein constituents. Plasma HDL is predominantly α -migrating while pre β -HDL accounts for only 2-14% (25,27). By two-dimensional agarose/native PAGE, α -migrating HDL were shown to consist of both

HDL₂ and HDL₃ while pre β -HDL consisted of 3 subfractions: pre β ₁, pre β ₂ and pre β ₃-HDL (reviewed in ref (15)). The physical properties and metabolism of the α -migrating HDL includes the HDL₁, HDL₂ and HDL₃ subclasses described above whereas pre β -HDL are distinct from these forms and represent cholesterol-poor HDL precursors.

Pre β -HDL consist of apoA-I, PL, various amounts of FC and are generally devoid of CE. Pre β ₁-HDL are 70-80 kDa in size and approximately 5 nm in diameter (25) while pre β ₂-HDL are significantly larger, on the order of 325 kDa and 10-12 nm in diameter (26,28). Pre β ₃-HDL are slightly larger than pre β ₂-HDL and are poorly characterized due to their very low abundance in human plasma.

The molecular basis accounting for the electrophoretic migration of α - and pre β -HDL was described by Davidson and coworkers (29). The difference between the two appears to be due to the presence of a neutral lipid core in α - but not pre β -HDL. While neutral lipids do not directly contribute to HDL surface charge, conformational changes in the surface apolipoproteins, primarily apoA-I, are believed to confer this effect. Some contribution may be made from phosphatidylinositol content, however, this has been disputed by some groups (15).

Pre β ₁-HDL are the most effective acceptors of cellular cholesterol due to a lower FC to PL ratio relative to HDL₂ and HDL₃ (30). Yancey and coworkers suggested that apoA-I initially associates with the cell membrane to form apoA-I/PL complexes and these complexes subsequently serve as the acceptors for cholesterol efflux (31).

Pre β ₂ and pre β ₃-HDL are thought to represent subsequent stages in the maturation of pre β ₁-HDL, those particles which have accumulated significant levels of FC and PL from cells. However, pre β _{2,3}-HDL may also be generated directly during TRL lipolysis or HDL

remodeling. Several studies suggest that pre β -HDL are converted into α -migrating HDL. When plasma is incubated at 37°C for 90 min, total pre β -HDL content decreases by 33% (32). Under conditions in which LCAT activity is inhibited, a decrease in pre β -HDL does not occur, suggesting conversion of FC to CE is necessary for the conversion of pre β - to α -migrating HDL. Other work indicates that during similar incubations the association of apoA-I with pre β -HDL decreases over time with a parallel increase in that associated with α -migrating HDL and this shift was prevented by LCAT inhibition (32).

1.3.2.3 LpA-I and LpA-I:A-II

The second major apolipoprotein of HDL, apoA-II, defines two HDL subclasses, those particles containing apoA-I without apoA-II (LpA-I) and those containing apoA-I and apoA-II (LpA-I:A-II). Elevated levels of LpA-I are associated with decreased risk of atherosclerosis while no correlation is observed for LpA-I:A-II (33-36) suggesting these subclasses differ in their functional properties.

ApoA-II binds with greater affinity to PL than apoA-I and displaces apoA-I from HDL *in vitro* (37). However, when an apoA-II to apoA-I ratio in the physiological range (0.5:1.0) was used, apoA-II induced a rearrangement in apoA-I structure, enhanced apoA-I susceptibility to denaturation and decreased LCAT reactivity without appreciable apoA-I displacement (38). Addition of apoA-II was also found to render the central domain of apoA-I (residues 99-187) more accessible to proteolytic digestion.

HDL containing only apoA-II are undetectable *in vivo* but are easily generated *in vitro* (39). LpA-I and LpA-I:A-II appear equivalent with respect to their capacity to promote cholesterol efflux in most studies (40,41) however, some reports consider LpA-I better acceptors of cellular cholesterol (42-44). Lipid-free apoA-II recruits PL from cell

membranes as efficiently as does apoA-I, however apoA-II/PL complexes cannot be transformed to α -HDL by LCAT. This suggests the contribution of apoA-II to the pool of HDL precursors (pre β -HDL) and subsequent generation of CE-rich HDL is limited.

ApoA-II appears to modulate the activity of factors involved in HDL metabolism. Studies with apoA-II transgenic (45,46) and knock-out (47) mice suggests apoA-II inhibits HL activity. Zhong *et al.* observed that coexpression of apoA-II with CETP resulted in TG-enriched HDL, resistant to reductions in size and apoA-I content, reflecting inhibition of HL by apoA-II (46). Thus apoA-II may be a physiological inhibitor of HL activity and maintain steady-state concentrations of HDL by inhibiting HL-mediated HDL remodeling and catabolism. *In vitro* studies addressing this issue are controversial and have shown apoA-II both stimulates (48) and inhibits (49) HL activity.

1.3.2.4 *Discoidal and Spherical HDL*

For a complete description of the methodology used for visualizing lipoproteins by negative stain electron microscopy please refer to a review by Forte *et al.* (50). Newly isolated plasma lipoproteins are traditionally visualized by the negative staining technique using an electron dense stain such as uranyl acetate, uranyl formate, ammonium molybdate and phosphotungstate. HDL are predominantly 'spheroidal' in morphology and, when applied at high concentrations, form hexagonal packing arrays. Examination of HDL from individuals with familial LCAT deficiency and fish-eye disease reveals the presence of predominantly 'disc-shaped' (discoidal) HDL. Discoidal HDL likely represent intermediates in the formation of spherical HDL. In support of this hypothesis, lymph HDL, which represent newly synthesized intestinal HDL precursors, are discoidal (51). Reconstituted HDL formed *in vitro* by the cholate dispersion method exhibit both pre β -mobility and

discoidal morphology (52,53). Incubation of both plasma from LCAT deficient patients and reconstituted discoidal HDL with purified human LCAT *in vitro* results in the formation of spherical HDL and a shift to α -electrophoretic mobility (54,55). Thus pre β - and α -migrating HDL may be synonymous with discoidal and spherical HDL, respectively.

1.3.3 The Reverse Cholesterol Transport Hypothesis

Research interest in HDL is derived from the findings of epidemiological studies which have established an inverse correlation between HDL cholesterol levels and the risk of coronary artery disease (56-62). In support of this protective effect, *in vitro* studies have described several potential anti-atherogenic mechanisms for HDL (Table 1-3). However, the most widely accepted explanation is that of the reverse cholesterol transport pathway. First proposed by Glomset in 1968, it has remained essentially the same since its inception (10). HDL acquire cholesterol from peripheral tissues, including cells within the arterial wall, and mediate its transport to the liver for biliary excretion and recycling (Fig. 1-3). By mitigating

Figure 1-3: Schematic of the Reverse Cholesterol Transport Pathway

Nascent HDL (pre β_1 -HDL) acquire FC and PL from peripheral cells by efflux mechanisms involving ABCA1 forming larger pre $\beta_{2,3}$ -HDL. Discoidal, pre β -HDL are converted to spherical, α -migrating HDL_{2,3} by the partitioning of LCAT-derived CE to the HDL core. HDL-CE is transferred to the apoB-100 containing lipoproteins and subsequently taken up by the liver via interaction with the LDL receptor. Alternatively, some HDL-CE may be taken up directly by selective uptake involving SR-BI or conversion of HDL₂ to HDL₁ and receptor-mediated endocytosis involving the LDL receptor and LRP.

the accumulation of excess cholesterol, HDL protect against the formation of cholesterol-engorged macrophages within the arterial wall and the subsequent development of atherosclerotic lesions. This section describes the key steps in this pathway.

1.3.3.1 Origins of HDL Precursors

As opposed to chylomicrons and VLDL that are assembled intracellularly and secreted, HDL appear to be assembled within the circulation from apolipoprotein and lipid constituents derived from various sources. Spherical, α -migrating HDL originate from HDL precursors, particles consisting of apoA-I and minimal amounts of lipid, referred to as nascent HDL.

Preliminary experiments using rat liver perfusion identified discoidal complexes, proposed to be nascent HDL (80). However, apoE but not apoA-I was the major apolipoprotein component of these structures suggesting they are not precursors to mature HDL, which contain predominantly apoA-I. Similarly, electron microscopic examination of intestinal lymph revealed the presence of discoidal structures. However, in contrast to hepatic perfusates, apoA-I was the predominant apolipoprotein (81).

The inability to detect mature HDL along the cellular secretory pathway in liver and intestinal cells further suggested these particles are not the secretory products of cells, while intact VLDL and chylomicrons were identified by this technique (80,82). Nonetheless, hepatic production rate of apoA-I is a major determinant of plasma HDL levels. Sorci-Thomas *et al.* demonstrated that isocaloric substitution of polyunsaturated fat reduced HDL concentrations in African green monkeys and correlated with reduced hepatic secretion of apoA-I during liver perfusion (83). Similarly, a comparison of cynomolgus and African green monkeys indicated that hepatic secretion rate of apoA-I was 5-fold greater in African green monkeys, which have 2- and 2.7-fold greater plasma levels of HDL cholesterol and apoA-I than cynomolgus monkeys (84). Furthermore, higher plasma levels of HDL correlated with a greater resistance to diet induced atherosclerosis in the African green monkey. These experiments suggest that while HDL may not be assembled within the cell, cellular production rate of apoA-I is responsive to dietary lipid status and directly related to plasma HDL levels.

Lipoprotein lipase (LPL) hydrolyzes core TG in chylomicrons and VLDL and its activity is dependent upon its cofactor apoC-II. Direct interaction of apoC-II with the N-terminal domain may represent the method of activation of LPL (85). LPL is localized

predominantly on the luminal side of endothelial cells, in proximity to sites of TG storage and utilization, adipose and muscle tissues that are the predominant sites of LPL synthesis.

LPL activity is directly related to plasma HDL concentrations and hydrolysis of chylomicron and VLDL core TG contributes surface components including PL, FC and apolipoproteins to the HDL pool (86,87). LPL or apoC-II deficiency is associated with elevated plasma TG, VLDL-C and apoB and low LDL-C and HDL-C consistent with impaired catabolism of TRL and impaired generation of HDL precursors.

The lipidation of nascent HDL was recently shown to depend upon phospholipid transfer protein (PLTP). PLTP is a 476 amino-acid glycoprotein (88) and a member of the lipopolysaccharide binding/lipid transfer protein family, which also includes cholesteryl ester transfer protein (CETP), lipopolysaccharide-binding protein (LBP) and bactericidal/permeability-increasing protein (BPI) (88,89).

In vitro studies have demonstrated that PLTP transfers PL (90), α -tocopherol (91), lipopolysaccharide (92) and FC (93) between lipoprotein particles. In doing so, PLTP modified HDL particle size distribution and, subsequently, was proposed to be important for HDL metabolism *in vivo*. The most convincing evidence for this has been published recently using PLTP transgenic and knock-out mouse models. Jiang *et al.* demonstrated that PLTP deficient mice were unable to transfer phosphatidylcholine from intravenously infused VLDL to HDL particles, which resulted in enhanced HDL catabolism and low HDL and apoA-I levels (94). However, studies in which PLTP was overexpressed were inconsistent with these observations. Transgenic mice or mice expressing high levels of human PLTP by adenovirus-mediated gene transfer exhibited decreased apoA-I and HDL levels (95-97). Human PLTP transgenic mice exhibited a 30-40% decrease in plasma levels of HDL and incubation of plasma from these mice at 37°C revealed a 2- to 3-fold increase in the

formation of pre β -HDL relative to wild-type mice (96). While pre β -HDL are normally a minor subfraction of HDL, this species is a very efficient acceptor of cellular cholesterol and

Figure 1-4: Sources of HDL Precursors

Nascent HDL are derived from hepatic and intestinal secretion, lipolysis of triglyceride-rich lipoproteins (TRL) and HDL remodeling.

a key component to reverse cholesterol transport. Therefore, PLTP is proposed to have an anti-atherogenic effect by mitigating accumulation of excess cholesterol via generation of pre β -HDL. Pre β -HDL are also generated by HDL remodeling involving CETP and HL and is described in Section 1.3.3.4. The sources of HDL precursors are summarized in Fig. 1-4.

1.3.3.2 HDL-Mediated Removal of Cellular Cholesterol: Tangier Disease and ABCA1

Cholesterol efflux refers to the net movement of cellular FC to an extracellular acceptor particle, a process that opposes the accumulation of excess cholesterol by cells *in*

in vivo and is subdivided into two general forms (reviewed in ref (98)). The first is 'diffusional' efflux, which concerns the net movement of cholesterol from cell membranes to a lipoprotein or another acceptor particle through aqueous phase at below critical micelle concentration (99-101). The process is non-directional and the rate-limiting step is desorption of cholesterol from the plasma membrane. This varies depending upon cell type (102,103), properties of the cell membrane and LCAT activity, which maintains a concentration gradient of FC between the cell membrane and the lipoprotein surface driving the net transfer to the lipoprotein (10).

The finding that lipid-free apolipoproteins induced cellular cholesterol release (104) formulated the second type referred to as 'apolipoprotein-specific' cholesterol efflux sometimes referred to as binding and translocation dependent efflux. While this mechanism is only partially defined, it involves the direct interaction of exchangeable apolipoproteins with the cell followed by the efflux of cholesterol and PL to the acceptor protein. As opposed to the diffusional mechanism, the apolipoproteins initially recruit PL, probably from the cell surface, forming apolipoprotein/phospholipid complexes that subsequently recruit cholesterol forming HDL particles (105).

The classification of HDL as products of the remnants derived from the lipolysis of chylomicrons and VLDL (proposed by Eisenberg (106)) now seems inadequate. The importance of cellular lipid acquisition by HDL precursors has emerged following the identification of ABCA1 as the affected gene in Tangier disease. This discovery clearly demonstrated that cholesterol efflux mechanisms involving lipid-free/poor apolipoproteins are essential for maintenance of steady-state concentrations of HDL and supports the role of reverse cholesterol transport in cellular cholesterol homeostasis.

Tangier disease (TD) is an autosomal recessive disorder first identified in a kindred from Tangier Island, Virginia (recently reviewed in ref (107)). The most striking features of these individuals are hyperplastic, orange tonsils present in approximately one-third of the less than 100 cases documented to date. Clinical presentation of TD is variable and may involve splenomegaly, hypocholesterolemia, ocular abnormalities, peripheral neuropathy and coronary artery disease. Biochemical features include HDL deficiency, elevated plasma TG levels and peripheral storage of CE in various cell types. The most prominent cell types accumulating CE belong to the reticulo-endothelial system, however other cell types accumulate CE as well, including the fibroblasts of the cornea, melanocytes, Schwann cells, neurons and non-vascular smooth muscle cells.

The most prominent lipoprotein phenotype associated with this disease is the virtual absence of α -migrating HDL and apoA-I levels reduced to 1-3% of normal values (108) despite normal apoA-I structure and apoA-I synthetic rate (109). The only HDL species present in these patients is pre β_1 -HDL, a lipid-poor HDL precursor normally of low abundance in plasma.

The accumulation of cholesterol in TD reflects an imbalance in cellular cholesterol homeostasis. In this regard, several laboratories demonstrated that fibroblasts isolated from Tangier patients had defective cholesterol efflux (110-112). Cell culture studies indicated that efflux of cholesterol to HDL and cyclodextrin (111) was normal in Tangier fibroblasts while efflux to apoA-I was virtually absent relative to controls (111,113).

In 1999, three groups identified mutations in the gene encoding for the ATP binding cassette transporter A1 (ABCA1) as the TD gene (114-116). This was a previously cloned member of a large protein family known as the ATP binding cassette transporters (reviewed in ref (117)). More recently, Marcil *et al.* demonstrated that mutations in ABCA1 are also

associated with many cases of hypoalphalipoproteinemia and familial HDL deficiency (FHD) (118).

The topology of ABCA1 is similar to that of the cystic fibrosis transmembrane conductance regulator (CFTR), consisting of 2 transmembrane domains each consisting of 6 putative transmembrane helices. Intracellularly, between the 6th and 7th transmembrane sequence are situated Walker A and Walker B motifs found in many proteins that utilize

Figure 1-5: Putative Topology of the ATP Binding Cassette Transporter A1

The schematic of the ATP binding cassette transporter A1 (ABCA1) illustrates the 2 sets of 7 transmembrane helices and 2 sets of intracellular Walker A and B motifs. Distal to the first set of Walker motifs a hydrophobic loop is thought to penetrate into but not through the plasma membrane.

Adapted from Hayden *et al.* (119)

ATP (Fig. 1-5) (120). ABCA1 is associated predominantly with the plasma membrane where it may act as a PL (and cholesterol) ‘flippase’, transferring these molecules from the inner to the outer membrane leaflet where they are accessible to surface bound apolipoproteins (121,122). While the tertiary structure of ABCA1 is unknown, by analogy to a close family member, P-glycoprotein, this transporter likely forms a large aqueous pore in the plasma membrane in which the Walker A and B motifs are in close proximity (123). Lipid-free apolipoproteins may interact directly (124,125) or indirectly (126) with ABCA1, stimulating the mobilization of intracellular cholesterol in transport vesicles or ‘rafts’ in a Golgi-

dependent process to the plasma membrane. ABCA1 translocates the lipid domains to the exofacial side of the plasma membrane where they form structures protruding from the cell surface. Interaction of apolipoproteins solubilizes these domains generating small HDL particles.

1.3.3.3 HDL Maturation: The Role of LCAT

Lecithin:cholesterol acyltransferase (LCAT) was first identified by Glomset in 1962 and is a plasma enzyme that catalyzes the hydrolysis and transfer of the sn-2 fatty acyl chain of phosphatidylcholine (lecithin) to FC forming lysophosphatidylcholine and CE (reviewed in refs (127,128)). CE is the predominant storage form of cholesterol both in cells and in lipoproteins. Furthermore, the majority of CE in plasma is derived from LCAT esterification. HDL is the preferred lipoprotein substrate for LCAT, which requires activation by apoA-I for maximal enzymatic activity. Due to increased hydrophobicity, esterification induces a repositioning of the cholesterol molecule from the HDL surface to the core where it is no longer directly exposed to the aqueous environment. The accumulation of CE in the HDL core *in vitro* is concomitant with the transformation of pre β - to α -migrating HDL and discoidal to spherical HDL.

LCAT is a glycoprotein with an apparent molecular weight of 60 kDa, of which glycosylation accounts for approximately 20%, synthesized in the liver and present both free in the circulation and bound to lipoprotein surfaces. The secondary structure of LCAT contains both β -sheet and α -helical elements organized into an α/β hydrolase fold similar to other members of the lipase gene family (129).

The importance of LCAT for formation of native HDL in plasma was first evidenced by the aberrant HDL metabolism in familial LCAT deficiency (FLD) and fish-eye

disease (FED) (reviewed in ref (130)). Both disorders are characterized by extremely low or nonexistent plasma LCAT activity, markedly decreased lipoprotein CE content, abnormal lipoprotein profiles and morphologically abnormal erythrocytes. In FED, LCAT activity associated with HDL is defective while LDL cholesterol is esterified normally, in contrast to FLD in which both activities are abnormal. Electron microscopic examination of HDL from these individuals indicated they were predominantly of discoidal morphology. Incubation of plasma from FLD and FED patients with purified human LCAT induced a transformation from discoidal to spherical morphology, suggesting plasma LCAT activity is required for the proper conversion of discoidal to spherical HDL *in vivo*.

Overexpression of human LCAT in mice and rabbits (131-134) results in high plasma LCAT activity and increased HDL cholesterol apparently due to decreased catabolism of large HDL by the liver and increased hepatic apoA-I production in transgenic rabbits (135). When fed a high cholesterol diet, LCAT transgenic rabbits were significantly protected from atherosclerosis as compared to controls not expressing human LCAT, while LCAT transgenic mice are more susceptible to diet induced atherogenesis (136,137). This appears to be due to the presence of CETP in rabbits and its absence in mice. The larger, cholesterol-rich HDL generated in the absence of CETP were cleared more slowly by the liver and were proatherogenic.

Therefore, plasma LCAT activity is critical for the conversion of lipid-poor HDL precursors, discoidal and pre β -HDL, to spherical α -migrating HDL₂ and HDL₃. Esterification of HDL free cholesterol maintains a concentration gradient driving the net transfer of cholesterol from cell membranes to HDL, a crucial step for reverse cholesterol transport.

1.3.3.4 HDL Remodeling

'Remodeling' refers to the processes that alter the biochemical and physical properties of CE-containing HDL in the circulation. This involves the combined actions of CETP, HL and PLTP, which modulate the lipid composition and plasma levels of HDL. These processes serve to transfer LCAT-derived CE from HDL to apoB-100 containing lipoproteins allowing subsequent uptake by the liver and regeneration of HDL precursors.

CETP is a hydrophobic glycoprotein with an apparent molecular weight of 70-74 kDa synthesized in liver, spleen, small intestines, adipose tissues, adrenal gland, kidney, heart and skeletal muscles (138,139). CETP expression varies greatly between species, being very low in mice and high in rabbits whereas activity in humans is intermediate (140). CETP reversibly associates with lipoproteins within the circulation and mediates bi-directional lipid exchange from one lipoprotein particle to another. CETP facilitates the transfer of CE from HDL to VLDL, IDL and LDL while TG moves simultaneously in the opposite direction in an equimolar ratio (138). IDL and LDL are catabolized in the liver and mediate the ultimate clearance of HDL cholesterol from the circulation via interaction with the LDL receptor. This exchange also results in TG-enriched HDL subject to lipolysis by hepatic lipase.

HL is a lipolytic enzyme structurally similar to LPL that is synthesized in hepatocytes and bound to the basolateral surface of hepatocytes and hepatic endothelial cells facing the space of Disse (141,142). Unlike LPL, HL does not have an absolute requirement for an apolipoprotein cofactor for enzymatic activity. The substrate specificity of HL is broad *in vitro*, therefore designating a specific metabolic role for this enzyme has proved difficult.

In concert, CETP and HL serve to deplete large HDL particles of CE and regenerate pre β -HDL and HDL₃ species which can scavenge additional lipid from cellular membranes (Fig. 1-6). CE transferred to apoB-containing lipoproteins are taken up in the liver via

interaction with the LDL receptor by receptor-mediated endocytosis, serving as the final step in the HDL mediated retrograde transport of cholesterol.

Figure 1-6: Combined Actions of CETP and HL in HDL Remodelling

CETP mediates the heterotypic exchange of HDL-CE for TG from VLDL, IDL and LDL resulting in the TG enrichment of HDL₂. The TG content of HDL₂ is subject to hydrolysis by HL resulting in the liberation of excess surface components, including FC, PL and apolipoproteins (apoA-I), forming nascent pre β -HDL and smaller HDL₃.

1.3.4 SR-B1: Selective Uptake of HDL Cholesterol

Scavenger receptors are a structurally diverse class of receptors that bind a wide range of chemically modified and native lipoproteins (reviewed in ref (143)). The best characterized of these are the scavenger receptors class A type I and type II (SR-AI/II) and CD36 which are expressed on macrophage and appear to play an important role in the uptake and accumulation of oxidized LDL. A novel mechanism of cellular cholesterol uptake from lipoproteins, called selective uptake, was first described in cell culture studies (144). This involves the cellular uptake of HDL CE in the absence of appreciable internalization of the HDL particle. The scavenger receptor class B type I (SR-BI) was cloned based upon its ability to bind acetylated LDL (145) but has also been shown to bind native lipoproteins including HDL and LDL. In addition to binding, SR-BI mediates the selective uptake of lipids from HDL (146) and LDL (147) in transfected cells. SR-BI is

abundant in liver and steroidogenic tissues and correlates with selective uptake activity of HDL cholesterol in these tissues.

The suggested importance of SR-BI in HDL metabolism is evidenced *in vivo* using adenovirus-mediated gene transfer and transgenic techniques. Overexpression of hepatic SR-BI significantly reduces HDL cholesterol and increases cholesterol in the bile (148,149). Genetic ablation of SR-BI resulted in increased plasma HDL cholesterol associated with larger HDL particles relative to wild-type animals (150). Furthermore, SR-BI deficient mice exhibited reductions in the cholesterol content in steroidogenic tissues (150). These results indicated that in the absence of SR-BI both liver and steroidogenic tissues exhibit reduced selective uptake of HDL CE. This suggests that, at least in mice, selective uptake of HDL cholesterol may be a major route for hepatic cholesterol clearance with respect to reverse cholesterol transport. However, there is no evidence that selective uptake of HDL cholesterol is a major route for hepatic clearance in humans.

1.3.5 HDL Catabolism

Several studies suggest that enhanced catabolism and not production rate is the principal metabolic determinant of plasma HDL levels (151,152). HDL clearance rates from plasma are inversely correlated to particle size, as smaller HDL have shorter residence times than larger HDL. Thus lipolytic enzyme (153) and lipid transfer protein activities can regulate the catabolic rate of HDL by changes in HDL particle composition.

TG-enrichment of HDL has been shown to increase lipolysis of HDL by HL, reduce HDL size and increase particle catabolism (154,155). Similarly, hypertriglyceridemia is often associated with low plasma HDL levels, TG-rich HDL and a greater fractional catabolic rate of apoA-I (156). Enrichment of HDL with TG *in vitro* followed by subsequent lipolysis with

LPL results in enhanced rate of clearance when infused into rabbits (157). *In vivo*, the plasma factor responsible for TG enrichment of HDL is CETP, which mediates the exchange of HDL CE for TG from VLDL, IDL and LDL. Subsequent hydrolysis by HL results in the formation of smaller HDL particles and the generation of nascent pre β -HDL. *In vitro*, hydrolysis of HDL TG promotes the dissociation of apoA-I (158), suggesting that HDL in hypertriglyceridemic individuals may contain a greater proportion of loosely associated apoA-I, which is more rapidly cleared from the circulation by renal filtration (157). Furthermore, Braschi *et al.* demonstrated that the charge and conformation of apoA-I in reconstituted lipoproteins may be key factors in determining the clearance rates of apoA-I and HDL from plasma (159).

1.4 Apolipoprotein A-I Structure and Function

Many of the functional and anti-atherogenic properties of HDL are conferred by its principal protein constituent, apoA-I. ApoA-I is a 243 a.a. plasma protein secreted from both liver and intestine and is one of the most abundant apolipoproteins in mammalian blood plasma. ApoA-I stimulates the removal of excess cholesterol from various cell types, serves as a cofactor for LCAT and thereby mediates the assembly of HDL within the circulation. This section describes in detail the gene organization, protein structure, structure-function relationships and animal models used to characterize apoA-I.

1.4.1 ApoA-I Gene Structure

The human apoA-I gene is located on the long arm of chromosome 11 (11q23) in a multigene complex with apoC-III and apoA-IV which spans over 15 kb (160,161). The gene is organized in a manner similar to the other mammalian exchangeable apolipoproteins with the exception of apoA-IV, consisting of 4 exons and 3 introns (Fig. 1-7) (reviewed in ref (162)). The first intron interrupts the 5' untranslated region while the second is situated within the coding sequence upstream of the signal peptidase cleavage site. The third intron interrupts the coding sequence at codon 43 and thus codons 44-243, which encode the remainder of apoA-I, are derived from exon 4. The first 3 exons are the most highly conserved amongst the exchangeable apolipoproteins while differences in mRNA length are mainly due to the length of exon 4. The remarkably similar genomic structure of this family supports the hypothesis that they evolved from a common ancestor by partial and complete gene duplications (Fig. 1-8).

Figure 1-7: Intron / Exon Arrangement and Coding Sequences of the ApoA-I Gene

The wide bars represent exons while thin lines represent introns. Exons are further subdivided: the open bars represent the 5' and 3' untranslated regions, the hatched bars mark the region encoding the signal peptide and the black bars indicate the regions encoding the mature protein. In addition, the grey bar in exon 3 represents the 6 residue signal peptide. Adapted from Luo *et al.* (163).

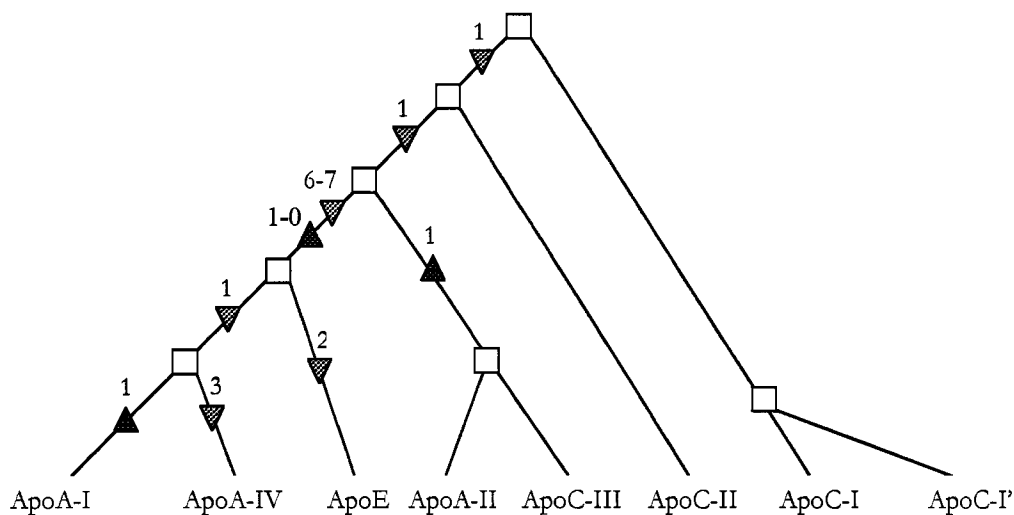

Figure 1-8: Evolutionary Tree of the Plasma Exchangeable Apolipoproteins

The initial ancestor was likely very similar to apoC-I in structure and length. Full gene duplications (□) followed by subsequent duplications of 22 or 11 codons (▼) and deletions of 11 codons (▲) generated the 6 other family members. Adapted from Luo *et al.* (163).

1.4.2 ApoA-I Protein Structure

This section serves to review the current models of apoA-I primary, secondary and tertiary structure. While some models suggest dimeric interactions of apoA-I may occur when bound to HDL, this has been poorly characterized and thus potential models of quaternary structure will not be considered aside from the putative lipid-bound topology.

1.4.2.1 ApoA-I Synthesis and Primary Structure

Plasma apoA-I is secreted from both human liver and intestine (106,164,165). Initially synthesized as a 267 a.a. preproprotein, the 18 a.a. pro-sequence is cleaved following ER translocation and apoA-I is secreted into the circulation as a 249 proprotein (reviewed in ref (166)). The hexapeptide pro-peptide is rapidly removed within the circulation by an unidentified enzyme generating the mature 243 a.a. protein. Recent work by Pyle *et al.*

suggests this enzyme is a metalloprotease, as the cleavage event was inhibited by metalloprotease inhibitors and was dependent upon calcium, and recognizes a consensus sequence encompassing residues -2 to +4 of proapoA-I (167). Furthermore, the work of Stoffel *et al.* suggests this cleavage may be dependent upon the conformation of this region (166).

ApoA-I from a number of species, ranging in size from 258-267 a.a., show considerable sequence similarity (45-55%) (Fig. 1-9) (162,168). A comparison of the aligned sequences indicates the amino-terminal domain (residues 1-98) is most highly conserved, consistent with the studies of Collet *et al.* demonstrating that the immunoreactivity of monoclonal antibodies is most highly conserved in this region while the remainder of apoA-I exhibits conservative substitutions (169). As indicated above, residues 1-43 of the mature sequence are encoded by exon 3 while the remainder of the protein is derived from exon 4. The primary structure encoded by exon 4 of the exchangeable apolipoproteins (exon 3 for apoA-IV) contains multiple repeats of 22 amino-acids which are punctuated by single Pro residues in most instances. The conservation of the 22-mer repeats and the positions of the prolines further suggest a common origin for the exchangeable apolipoprotein gene family.

1.4.2.2 *ApoA-I Secondary Structure: The Amphipathic α -Helix*

These tandem repeats of 22 amino-acids form amphipathic α -helices, which Segrest *et al.* first described as unique structural motifs in lipid interaction (170). An amphipathic helix is defined as an α -helix with opposing polar and non-polar faces oriented along the long axis of the helix and, while initial identification was confined only to the apolipoproteins, they have since been identified in many functionally diverse proteins.

Figure 1-9: Alignment of Human ApoA-I with Sequences from 11 Species

The primary (prepro-) sequences of apoA-I from human (171), baboon (172), dog (173), pig (174), rabbit (175), cow (176), hedgehog (177), mouse (178), rat (179), chicken (180), duck (Swiss-Prot accession number, O42296) and salmon (181) are aligned. Colors indicate proline (purple, P), aspartic acid or glutamic acid (red, D and E), arginine or lysine (blue, R or K), and phenylalanine, isoleucine, leucine, methionine, valine, tryptophane, or tyrosine (green, F, I, L, M, V, W, and Y). The remaining amino acids, alanine, cysteine, glycine, histidine, asparagine, glutamine, serine, and threonine (A, C, G, H, N, Q, S, and T) are uncolored. The numbering of human apoA-I starts at -24 (signal peptide of apoA-I), residue 1 being the first of mature apoA-I.

Early predictions of apoA-I secondary structure employed the sequence algorithms described by Chou and Fasman (183). These studies suggested residues 44-243 of apoA-I may be composed of 8-10 α -helices formed predominantly by 22-mer and 11-mer repeats while the N-terminus (a.a. 1-43) assumes a less well-defined globular structure (184,185). This was partially confirmed experimentally by circular dichroism and infrared spectroscopy (52,186,187). Structural analysis by Segrest *et al.* generated similar results with respect to the exon 4 encoded region and suggested that residues 8-33 form an amphipathic helix similar to those found in some globular proteins (188). More recently, 10 amphipathic helices spanning residues 44-243 have been identified in the crystal structure of an apoA-I deletion mutant lacking residues 1-43 (189).

The amphipathic helices were initially divided into seven varieties based upon the proteins in which they were first identified: class A (apolipoproteins), class H (polypeptide hormones), class L ("lytic" polypeptides), class G (globular proteins), class K (calmodulin-

regulated protein kinases), class C (coiled-coil proteins) and class M (transmembrane proteins) (reviewed in ref (190)). More recent work has indicated the apolipoproteins are composed of class A₁, class A₂, class Y (all slight variants of the original class A) and a class G variant (referred to as class G*) (188). The physical properties and distribution of charged residues in these helices are indicated in Table 1-4 and Fig. 1-10, respectively. Class A₁ and A₂ are very similar, positive charges are symmetrically distributed at +/- 100° while negative charges form a single cluster and are directly opposite the hydrophobic face for both classes. They differ structurally in that the positive-negative charge clustering is less well defined for A₁ than A₂ and, while the hydrophobicity of the nonpolar face is comparable, the hydrophobic moment and the Lys/Arg ratio is significantly lower for class A₁. Class Y differs significantly from both class A₁ and A₂ with respect to the organization of negative

and positive charges on the polar face. An additional group of positively charged residues separates two clusters of negative charges and results in a hydrophobic moment and nonpolar face hydrophobicity intermediate as compared to other amphipathic helices. G*

amphipathic helices do not exhibit any clustering of positive or negative charges on the polar face and the only consensus sequence in this class is a group of Leu residues on the nonpolar face. These helices possess a high hydrophobic moment and a moderately high nonpolar face hydrophobicity. The distribution of class A, Y and G* helices in apoA-I is shown in Fig. 1-11. The class A helices are all of the A₁ variety, A₂ helices are present in apoA-II and apoC- I/II/III.

1.4.2.3 ApoA-I Tertiary Structure: Lipid-Free and Lipid-Bound Forms

As an exchangeable apolipoprotein, apoA-I exists in equilibrium between lipid-free and lipid-bound forms, the former of which may compose up to 8% of total plasma apoA-I. In the absence of a crystal structure for full-length apoA-I in the presence or absence of lipids, information to date is somewhat indirect. This section discusses the current models of apoA-I tertiary structure in both the lipid-free and lipid-bound forms.

Understanding of the lipid-free structure of apoA-I is so limited that all three major review articles published in the past year on apoA-I structure and functional relationships chose not to address this issue. The most convincing evidence to date includes comparisons

to crystal structures of other exchangeable apolipoproteins, *in vitro* proteolysis, tryptophan fluorescence and analytical centrifugation.

Characterization of exchangeable apolipoproteins from human and insects suggests that in the absence of lipids these proteins form compact, helical bundle structures in which the hydrophobic faces are sequestered within the core of the bundle. The amino-terminal domain of human apoE (residues 1-191), at a resolution of 2.5 Å, formed an anti-parallel bundle of four amphipathic helices. The hydrophobic residues formed the core of the bundle while charged amino-acids were positioned on the surface (191). Furthermore, inter- and intrahelical salt bridges are abundant and likely stabilize the helix bundle.

Apolipoprotein III (apoLp-III) is an exchangeable apolipoprotein from *Locusta migratoria* (locust). It is a component of low density lipoprotein and is involved in the transport of diglyceride from the fat body storage depot to flight muscles where it is the principal energy source (192). The crystal structure of apoLp-III consists of a bundle of five amphipathic helices (193) with proline residues located in inter-helical turns. In addition, the structure of apoLp-III from *Manduca sexta* (sphinx moth) was determined by three-dimensional NMR spectroscopy and is very similar to that of *L. migratoria* (194).

By analogy to the known structures of these apolipoproteins, a helical bundle organization of exchangeable lipoproteins is likely well conserved through evolution, suggesting apoA-I assumes this form as well.

The first evidence of a compact, helical bundle organization in apoA-I was provided by Roberts *et al.* (195). Using chymotrypsin and V_8 protease from *S. aureus* for limited proteolytic digestion, they observed that proteolysis was limited almost exclusively to the C-terminus (residues 187-243) with only limited digestion in the central domain encompassing residues 115-136. The resistance of the N-terminus to enzymatic digestion is consistent with

a compact structure with minimal exposure of the peptide backbone. Interestingly, sulfoxidation of methionines at 112 and 148 rendered sites in helix 1 (44-65), 2 (66-88) and 7 (165-187) accessible to digestion. This suggests that alteration of the amino-acid side chain size and/or charge can affect the stability of the tertiary structure.

Perhaps the most convincing evidence for a helical bundle organization of apoA-I comes from Maiorano *et al.* using tryptophan fluorescence (196). Trp residues in proapoA-I are located at -3, 8, 50, 72 and 108, perfect for analysis of the amino-terminal region. Steady-state fluorescence studies indicated that all Trp residues existed in non-polar environments and were highly protected from solvent exposure. Using time-resolved lifetime and anisotropy, they determined the shape of the monomeric form of proapoA-I is a prolate ellipsoid. These studies suggest that apoA-I adopts a compact, helical bundle tertiary structure in the absence of lipids similar to that described in other exchangeable apolipoproteins. Models of the potential lipid-free forms of apoA-I were proposed by Rogers *et al.* and are shown in Fig. 1-12 (197). ApoA-I may exist in equilibrium between a compact helical bundle organization and an elongated conformer resulting from the reversible unhinging of the bundle located between residues 66-87. The hydrophobic faces of these helices are exposed in the elongated conformer and available for lipid-binding. Therefore, opening of the helix bundle in this manner is thought to represent an intermediate in lipid-binding.

The manner in which apoA-I is oriented around the surface of both native and reconstituted HDL has yet to be resolved and is perhaps the most fundamental aspect of apoA-I and HDL structure still outstanding. Two models have been the focus of much attention during the past several years and are referred to as the 'Picket Fence' and the 'Belt' models of apoA-I (recently reviewed in ref (198)). Due to both the ease and uniformity of

preparation, reconstituted discoidal HDL rather than native HDL have been preferentially used to address these models.

Figure 1-12: Proposed Lipid-Free Conformational Equilibrium of ApoA-I

(A) Folded four helix bundle and (B) elongated, monomeric helical hairpin models are shown. The four helix bundle model was proposed initially by Roberts *et al.* (195), refined by Rogers *et al.* (199) and is similar to the X-ray crystal and NMR structures of other exchangeable apolipoproteins. The elongated conformer is derived from experiments using analytical ultracentrifugation and is thought to represent a lipid-free conformer of apoA-I. The dashed line represents the plane of unfolding in which the helical regions N-terminal to residue 70 dissociate from the helical bundle and expose the hydrophobic faces of the bundle for lipid binding. Adapted from Rogers *et al.* (199)

In the Picket Fence model the amphipathic α -helices of apoA-I surround the periphery of the discoidal phospholipid bilayer and are oriented parallel to the lipid acyl chains (Fig. 1-13). This model was initially widely accepted based upon studies using Fourier Transform Infrared (FTIR) spectroscopy that seemed to provide unequivocal evidence for the Picket Fence orientation of apoA-I in reconstituted lipoprotein films (186).

Subsequently, research interest was directed at elucidating the details of this model rather than testing its validity.

Phillips *et al.* have recently tested this model by computer modeling using a model discoidal lipoprotein containing 2 molecules of apoA-I and 160 molecules of POPC and found that large interhelical distances resulted in the exposure of 20% of the area of the lipid acyl chains to water (200). Presumably the energetics that drive the formation of discoidal lipoproteins depend on the removal of hydrophobic groups from the aqueous environment suggesting this model may not be thermodynamically favoured. Furthermore, they suggest that 2 apoA-I molecules would be unable to shield the entire hydrophobic edge of a discoidal lipoprotein. A surface area corresponding to greater than 25% of the total surface area was found to be solvent-exposed in this model.

Figure 1-13: Picket Fence Model of ApoA-I in Discoidal HDL

This model illustrates the topology of apoA-I in the context of a discoidal lipoprotein with the amphipathic helices oriented parallel to the lipid acyl chains. The N- and C-termini of each monomer are shown to the left and right of the figure, respectively. The 2 helices that are shown separated from the lipoprotein in panel A represent a potential hinge domain in apoA-I consisting of helices 4 and 5. This region may be important for the plasticity of the protein necessary for accommodating changes in HDL size and composition.

The 'belt' model differs significantly from the Picket fence model because apoA-I wraps around the periphery of the HDL particle perpendicular to the lipid acyl chains. This model was initially proposed based primarily upon the crystal structure of an apoA-I mutant lacking

residues 1-43 in the absence of lipids (189) (refer to Fig. 1-14). This deletion mutant of apoA-I adopts a pseudo-continuous amphipathic α -helix in a crystal structure consisting of an apoA-I dimer oriented in an antiparallel manner with extensive intermolecular interactions. Interestingly, the C-terminal helix (a.a. 227-243) of one monomer forms close contacts with the same helix of the other monomer that forms a closed horseshoe shaped structure which could potentially wrap around a discoidal HDL particle.

Figure 1-14: Crystal Structure of the Δ 1-43 ApoA-I Dimer in the Absence of Lipids

Two apoA-I monomers are shown oriented in an antiparallel manner with helix 10 from each protein forming a close molecular 'handshake'. Intermolecular interactions are located throughout the remainder of the dimer, as well, suggesting this structure may exist on the surface of HDL.

Originally published by Segrest *et al.* (201)

Reprinted with the permission of Lippincott Williams & Wilkins Ltd.

Biochemical evidence suggests this deletion mutant lacks the compact lipid-free tertiary structure of full-length apoA-I but retains most of its native lipid-binding properties (197). Subsequently, it was postulated that the crystal structure of Δ 1-43 apoA-I is representative of the lipid-bound structure of wild-type apoA-I in HDL. This model has

recently been supported by several spectroscopic analyses using discoidal reconstituted HDL (196,202,203). Segrest *et al.* have recently constructed a detailed molecular Belt model for discoidal HDL and found that in contrast to the Phillips *et al.* Picket Fence model, their Belt model resulted in the shielding of essentially all of the lipid acyl chains (204) (refer to Fig. 1-15C).

Figure 1-15: Potential Lipid-Bound Structures of ApoA-I

Panel A: This space-filling model illustrates the 'picket-fence' model of a dimer of apoA-I in discoidal lipoproteins. The amphipathic helices are oriented parallel to the phospholipid fatty-acyl chains.

Panel B: These models depict the lipid-bound topology of an apoA-I dimer in the 'belt' model in the context of a discoidal lipoprotein. Monomers are oriented in an anti-parallel fashion, however, in this model the amphipathic helices wrap around the periphery of the lipoprotein particle, perpendicular to the PL fatty-acyl chains. Both ribbon (top) and space filling (bottom) models are shown.

Panel C: This model is adapted from the 'belt' model and illustrates the proposed topology of 2 apoA-I dimers bound to a spherical HDL particle.

Originally published by Brouillette *et al.* (198)

Reprinted with permission of Elsevier Science

While arguments for both models remain, the Belt model has emerged as the best candidate.

However, it is still unclear if the belt orientation of apoA-I reflects its topology in spherical HDL as most direct evidence is derived from discoidal lipoprotein models. One model that has been presented, also based on the crystal structure of $\Delta 1-43$ apoA-I, consisted of four molecules of apoA-I on spherical HDL and is referred to as the 'Faberger Egg' (189). Two

dimers were placed on the surface of the HDL particle, passing one another where helices 10 were separated. The conversion of discoidal to spherical HDL is thought to occur via separation of the molecular 'handshake' occurring between apoA-I dimers which could allow for the incorporation of cholesteryl esters in the core of the lipoprotein particle in this manner.

1.4.3 ApoA-I Structure-Function Relationships

The study of apoA-I structure-function relationships is based largely upon the physical and biochemical properties of naturally occurring and engineered apoA-I mutants. The association of specific helical domains of apoA-I with lipid-binding, cholesterol efflux and LCAT activation is addressed.

1.4.3.1 Phospholipid Association

The association of apoA-I with PL is governed by amphipathic α -helices. When combined in the test tube, apoA-I spontaneously clears dimyristoylphosphatidylcholine (DMPC) vesicles at their transition temperature (23.9°C) to form 'disc-shaped' (discoidal) lipoprotein complexes (205-207). Similarly, incubation of apoA-I with POPC and the detergent sodium cholate results in the formation of discoidal lipoproteins (208,209). Incubation of these complexes with LCAT transforms these discs to spheres due to the accumulation of a CE core (210). Using circular dichroism, Segrest and coworkers demonstrated that apoA-I helical content increases upon lipid association from 40-50% to 75% depending upon the lipids used (52,211) suggesting an increase in apoA-I stability in the presence of lipids.

Observations from studies using synthetic peptides modeled after individual or multiple apoA-I helices and deletion mutants suggested apoA-I helices are not equivalent in

lipid affinity. Those helices having greater affinity for PL are proposed to constitute important lipid-binding domains within apoA-I. Palgunachari *et al.* demonstrated that only those peptides analogous to helix 1 (a.a. 44-65) and helix 10 (a.a. 220-243) were able to solubilize DMPC liposomes. This suggests both helix 1 and 10 are important domains which may mediate the initial association of apoA-I with PL (212).

The importance of helix 1 and 10 in lipid association has been confirmed using deletion mutants of apoA-I. Rogers and coworkers compared apoA-I mutants lacking residues 1-43 and 1-65 (referred to as Δ 1-43 and Δ 1-65 apoA-I) and found that the latter but not the former exhibited significantly reduced lipid-binding affinity relative to wild-type apoA-I (199). The role of helix 10 in binding lipids has been confirmed in various mutagenesis studies. Work in our lab indicates that deletion of residues 187-243 significantly impairs the ability of apoA-I to bind PL vesicles *in vitro* and form lipoprotein particles (213). Animal studies are consistent with *in vitro* findings as apoA-I mutants lacking residues 210-243, 217-243, 226-243 and 190-243 are catabolized more quickly following intravenous infusion in rabbits (214,215). The faster catabolic rate reflects the decreased lipid binding affinity that leads to rapid degradation of the partially lipidated apoA-I.

However, some natural apoA-I mutants in the central domain, Lys¹⁰⁷→0 and Δ 146-160 apoA-I, exhibit impaired lipid-binding (216,217). To address the role of helices in the central domain of apoA-I to lipid-binding, Frank *et al.* constructed deletions of residues 100-143, 122-165 and 144-186 (218). These deletions were found to have little effect on the kinetics of apoA-I association with DMPC, however, they did appear to have a reduced capacity for binding lipids and may not be capable of accommodating varying amounts of HDL PL. Recent work suggests residues 100-121 and 122-143 are important for PL binding *in vivo* (219). ApoA-I deletion mutants lacking these residues were found to associate with

less PL following adenovirus-mediated expression in apoA-I deficient mice. This domain is proposed to constitute a hinge domain in apoA-I that allows apoA-I to accommodate changes in the HDL structure, a hypothesis based upon studies with monoclonal antibodies.

Apart from helix 1, the contribution of the N-terminal domain (residues 1-99) to lipid-binding is poorly understood. Deletion of residues 88-98 reduced the α -helicity of the protein to 34% and significantly compromised the ability of apoA-I to clear DMPC liposome turbidity (199). This helix is one of two putative 11-mers in apoA-I. The deletion of this helix disrupts several structure and functional properties making its contribution to lipid-binding specifically difficult to ascertain.

While G* helices have a reduced affinity for PL as compared to class A and Y, Rogers *et al.* have shown that deletion of residues 1-43 impairs the ability of apoA-I to clarify a solution of DMPC liposomes (220). The potential importance for this region for PL-binding in apoA-I is supported by Mishra and colleagues demonstrating that a synthetic peptide modeled after residues 1-33 of apoA-I exhibits significant lipid-binding affinity relative to other apoA-I peptides (221).

The association of apoA-I with lipids is unlikely the simple sum of the interactions of each helix individually, as the cooperativity of apoA-I helices determines its native lipid-binding properties. Helices at the N- and C-terminus probably play important roles in the initial association of apoA-I with lipids and hence are considered important lipid-binding domains. Other helices may stabilize conformational changes during HDL maturation and remodeling and contribute to lipid association in this manner.

1.4.3.2 Cellular Cholesterol Efflux

As described in Section 1.3.3.2, cholesterol efflux is a process in which cholesterol is transferred from peripheral cells to apolipoprotein and HDL acceptor molecules (reviewed in ref (222)). Diffusional efflux involves desorption of cellular cholesterol by lipoprotein acceptor particles. This movement of cholesterol is passive and dependent upon a concentration gradient between the cell and acceptor particle, the capacity of the lipid surface for cholesterol acquisition and the desorption and adsorption rates of cholesterol (223-225). Glomset also proposed that HDL cholesterol esterification by LCAT may help maintain a concentration gradient driving the net transfer to the lipoprotein acceptor (10). Since the largest free cholesterol pool in the cell is the plasma membrane, this may represent the principal source of cholesterol for diffusional efflux. Phillips, Rothblat and coworkers have demonstrated that there appears to be at least two compartments in the plasma membrane available for cholesterol efflux (226-228). One is readily available for rapid release to a lipoprotein acceptor while the other is slow with respect to efflux out of the cell.

The observation that proteolytic treatment of HDL abolishes a major portion of the transfer of cellular cholesterol to HDL suggests that the apolipoprotein component of the acceptor particle may be important in regulating this form of cholesterol efflux (229). Initial studies using monoclonal antibodies to apoA-I suggested that specific domains in this protein may be directly involved in diffusional efflux of cholesterol as several groups implicated a domain including residues 74 to 150 in this process (230-232). Fielding *et al.* suggested that residues 137-144 are significantly more exposed in pre β -HDL relative to other HDL species making it more accessible for interaction with the cell surface (233). However, monoclonal antibodies to apoA-I can sterically interfere with domains other than the epitope itself (234) and modify secondary structural elements of apoA-I (235).

Studies using various deletion mutants of apoA-I were then conducted to address whether distinct domains in apoA-I are involved in diffusional cholesterol efflux. In these studies, synthetic lipoprotein complexes containing the respective apoA-I deletion mutants, phospholipids and cholesterol were used as the acceptor particles for cholesterol efflux. Work from several groups, including ours, has shown that apoA-I deletion mutants lacking residues 44-126, 139-170, 190-243, 222-243, 210-243, 150-243 and 135-243 were as effective as wild-type apoA-I when lipidated in mediating cholesterol efflux from fibroblasts (236,237). These results indicated that so long as the mutants could associate with PL they were not associated with altered cholesterol efflux and thus a specific domain in apoA-I is not required for diffusional efflux of cholesterol to HDL.

The apolipoprotein-specific or translocation dependent mechanism involves the efflux of cellular phospholipid and cholesterol to lipid-free apolipoproteins, those not associated with a lipoprotein particle. Two distinct phases appear to be involved in this process. Apolipoproteins initially bind to the cell and recruit phospholipids only (238). This binding can be upregulated by various agents that increase the activity of ABCA1 suggesting either that apolipoproteins bind directly to ABCA1 or that ABCA1 activity facilitates the interaction with alternative binding sites. Initial interaction with the cell is thought to result in the formation of apolipoprotein/phospholipid complexes that serve as acceptors for cellular cholesterol. This is corroborated by efflux studies using murine macrophage cell lines in which cholesterol efflux was induced by treatment with cyclic AMP, in parallel with apolipoprotein binding (239,240). Cholesterol for efflux to apolipoproteins is mobilized from an intracellular pool available for esterification by acylCoA:cholesterol acyltransferase (ACAT) and trafficks to the plasma membrane and appears to involve a specific intracellular signal rather than a general decrease of plasma membrane cholesterol (241,242). Caveolin-1

is a component of cholesterol and sphingomyelin-rich cell surface microdomains referred to as caveolae. Caveolin-1 enhances the transport of cholesterol from the intracellular compartment to the plasma membrane (243), forming a complex with chaperone proteins in the cytosol (244), and has been shown to be involved in cholesterol trafficking during apolipoprotein-mediated HDL generation (245).

While apolipoprotein-specific efflux can be elicited by various exchangeable apolipoproteins, apoA-I, apoA-II, apoA-IV, apoE and insect apoIII, and by synthetic amphiphilic peptides (31,104,246,247), some naturally-occurring mutations of apoA-I have a reduced ability to promote apolipoprotein-specific cholesterol efflux. Two of these mutations, Pro¹⁶⁵→Arg and Arg¹⁷³→Cys, likely cause significant alterations in the secondary structure of apoA-I and thus indirectly affect efflux. The mutation of Pro¹⁶⁵→Arg may remove a β -turn separating helices 6 and 7, which could affect the native lipid-binding properties of apoA-I and cholesterol efflux in a secondary manner. The substitution Arg¹⁷³→Cys results in the dimerization of apoA-I through a disulfide bridge and has been shown to modify the lipid binding properties of both the monomer and dimer. Studies in our lab have indicated that apoA-I mutants with deletions in the central domain had no effect on cholesterol efflux from fibroblasts when considered in the absence of LCAT (213,218).

Characterization of a natural single amino acid deletion, Glu²³⁵→0, in apoA-I suggested the C-terminus is important in cholesterol efflux as this mutant was associated with a 54% decrease in cholesterol efflux and reduced cell association relative to wild-type apoA-I (248). Efflux from cholesterol-loaded macrophage and association with DMPC was significantly impaired as compared to wild-type apoA-I suggesting functional lipid-binding of

the C-terminus is required for cholesterol efflux. Gillotte *et al.* suggested other helical domains in apoA-I may be important for this form of efflux (249). They demonstrated that synthetic peptides modeled after residues 44-56 and 209-241 of apoA-I were able to efflux cholesterol to a level 50% and 70% of full-length apoA-I, respectively, while peptides modeled after other apoA-I helices were not (249). This further suggested that PL-binding affinity correlates with cholesterol efflux and that the N-terminus of apoA-I (residues 44-65) may be important in this pathway, as well. Concerning the latter, the capacity of apoA-I N-terminal deletion mutants to elicit cholesterol efflux has not been characterized, however this domain has been shown to be important for lipid-binding (199).

1.4.3.3 Activation of LCAT

The physical chemical properties of the LCAT reaction have been intensely studied *in vitro* and demonstrate that LCAT binds not only to HDL but also LDL and PC vesicles. Studies from Jonas *et al.* using surface plasmon resonance have shown that the on-rate constants for LCAT interaction with all of these substrates are virtually equal and that apolipoprotein content does not affect this property (reviewed recently in ref (128)). However, the off-rate constants are dependent upon the apolipoprotein content and the nature of the surface lipids. Replacing apoA-I with apoA-II reduces binding affinity 4-fold, suggesting that LCAT initially binds to the lipid surface followed by a specific interaction and activation by apoA-I, the rate limiting of which appears to be PC binding at the active site (250). The off-rate constants in these studies were very similar to the catalytic turnover rates (0.01 - 0.05s⁻¹), suggesting that LCAT dissociates from HDL after an average of one catalytic cycle. General properties of the apolipoproteins associated with LCAT activation include: an amphipathic α -helix with a non-polar face of approximately 100°, a cluster of

acidic residues opposite the nonpolar face and a distribution of basic residues at the polar-nonpolar interface.

ApoA-I was the first described apolipoprotein activator of LCAT and also the most potent (251), as other apolipoproteins are less than 20% as efficient (252,253). These observations coupled with the fact that apoA-I is the principal protein component of HDL suggested this protein is critical for LCAT mediated CE accumulation in HDL. The observation that numerous apolipoproteins are able to stimulate LCAT activity to some degree suggested that amphipathic α -helices are necessary but not sufficient for this process. Therefore, detailed studies using synthetic peptides modeled after apoA-I helices, CNBr fragmentation and mutagenesis sought to reveal a specific domain(s) responsible for this process. Whereas diffusional cholesterol efflux closely correlated with the PL-binding affinity of apoA-I synthetic peptides, this was shown not to be the case for LCAT activation. Peptides modeled after the C-terminus (a.a. 187-243) of apoA-I could not bind and activate LCAT (254) while residues 148-185 were able to do so. Further studies indicated that peptides with high amphipathic character but no homology to apoA-I could activate LCAT (255,256). Segrest and coworkers found that such peptides gave maximal LCAT activation as a dimer and furthermore only when residue 13 was glutamic acid (257).

More recent work using apoA-I deletion mutants has established that helix 6 (a.a. 144-186) constitutes the principal LCAT activating domain. These studies are corroborated by analysis of naturally occurring apoA-I mutants: Lys¹⁰⁷→0, Leu¹⁴¹→Arg, Δ 146-160 apoA-I (Seattle), Arg¹⁵¹→Cys, Val¹⁵⁶→Glu, Leu¹⁵⁹→Arg, Pro¹⁶⁵→Arg and Arg¹⁷³→Cys which exhibit reduced LCAT activation (reviewed in ref (182)). Two *in vivo* studies support the putative role of this domain in LCAT activation. We have shown that both Δ 122-165 and Δ 144-186 apoA-I associate with CE poor HDL when expressed in apoA-I deficient mice by

adenovirus-mediated gene transfer (219). In contrast, $\Delta 100-143$ was not compromised in CE content. Sorci-Thomas and coworkers have generated a mouse transgenic for an apoA-I mutant lacking helix 6 (258). They observed this apoA-I mutant was associated with CE-poor HDL when crossed into a murine apoA-I deficient background. This is consistent with *in vitro* studies from their lab and ours concerning the role of this helix in LCAT activation (218,259). While the central domain has been implicated in LCAT activation for quite some time, the physical properties responsible have only recently been described. Roosbeek and coworkers proposed that 3 Arg residues at the polar/non-polar interface of helix 6 contribute to a specific region of positive electrostatic potential that may stimulate LCAT activity (260). Site-specific mutagenesis of these Arg residues conferred 11-12-fold reductions in LCAT activation (decrease in V_{max}) without affecting other physical properties of apoA-I. The studies to date clearly identify a central domain, most importantly helix 6, in LCAT activation. This may be due to the presence of a locale of positive surface potential

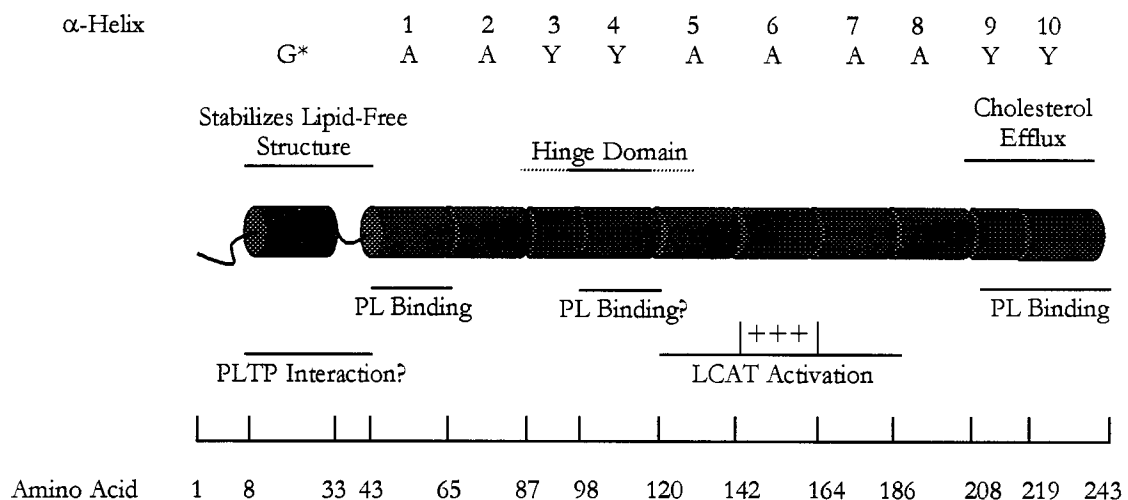

Figure 1-16: Putative Structure-Function Relationships of ApoA-I

involved in LCAT interaction. The secondary structural elements of apoA-I associated with specific functional properties are summarized in Fig. 1-16.

1.4.4 Characterization of ApoA-I and HDL Metabolism in Mouse Models

Genetic manipulation has enabled the development of transgenic and knockout (deficient) animals, which have served to establish the pro- or anti-atherogenic nature of various apolipoproteins, lipolytic enzymes, lipid transfer proteins and cell surface receptors. This section considers various animal models of apoA-I, which demonstrate its potent anti-atherogenic effects and importance in HDL formation.

1.4.4.1 ApoA-I Transgenic Mouse

Transgenic mice expressing high levels of human apoA-I were first described by Walsh *et al.* in 1989 (261). They reported plasma total apoA-I levels of 381 ± 43 mg/dL as compared to 153 ± 17 mg/dL for control mice. Total and HDL cholesterol levels were increased to 125 ± 12 mg/dL and 90 ± 7 mg/dL versus 78 ± 13 mg/dL and 55 ± 11 mg/dL for apoA-I transgenic mice and matched controls, respectively. Non-denaturing gradient gel electrophoresis demonstrated this increase in HDL was due predominantly to smaller HDL₃ type particles, the formation of which could not be attributed to aberrant metabolism of human apoA-I in these mice. In 1991, Rubin *et al.* described human apoA-I transgenic mice in a C57BL/6 background, a mouse strain susceptible to diet-induced atherosclerosis (262). In addition to increases in plasma total apoA-I and cholesterol levels, mouse apoA-I levels were reduced by greater than 4-fold and accounted for only 4% and 13% of total plasma levels in two independent transgenic lines. While wild-type C57BL/6 mice have a single HDL species, the apoA-I transgenic possesses two HDL subclasses comparable to HDL_{2b} and HDL₃ in humans. In support of epidemiological studies demonstrating the incidence of cardiovascular disease is inversely correlated to HDL cholesterol levels, the apoA-I

transgenic C57BL/6 mouse was protected from diet-induced development of fatty streak lesions relative to the wild-type mouse (263).

In 1994, two groups reported that the spontaneous atherosclerosis observed in apoE knockout (apoE^{-/-}) mice could be corrected by introducing a human apoA-I transgene (hapoA-I Tg). ApoE knockout mice are severely hypercholesterolemic and develop atherosclerotic lesions regardless of diet. Paszty *et al.* reported apoE^{-/-}-hapoA-I Tg mice had a 2 to 3-fold increase in HDL cholesterol and a six-fold decrease in susceptibility to atherosclerosis (264). Plump *et al.* indicated their apoE^{-/-} hapoA-I Tg had 2-fold increases in HDL cholesterol with reduced atherosclerosis and fibroproliferative lesions by 8 months of age (265).

1.4.4.2 ApoA-I Deficient Mouse

By gene targeting in embryonic stem cells, Williamson *et al.* generated an apoA-I knockout strain 129 mouse in 1992 to determine if mice lacking apoA-I were more susceptible to atherosclerosis (266). Plasma total cholesterol and HDL cholesterol levels were reduced to 26% and 25% of normal levels, respectively, and were deficient in α -migrating HDL particles. Interestingly, Li *et al.* reported apoE levels in these mice were increased 3-fold and constituted 1/3 of HDL protein as compared to wild-type strain 129 mice in which apoE is present at only trace levels in HDL (267). To investigate the effect of apoA-I deficiency on atherosclerotic risk, apoA-I deficient and wild-type strain 129 mice were maintained on an atherogenic diet for 4 weeks. During this period total plasma cholesterol levels increased by 20 mg/dL and 60 mg/dL in apoA-I deficient and normal mice, respectively, however neither group exhibited any early signs of atherogenesis. ApoA-I deficient strain 129 mice were crossed into C57BL/6 mice to study apoA-I deficiency in

mice susceptible to atherosclerotic lesions. These mice with mixed strain 129 and C57BL/6 genetic backgrounds were maintained on a high fat diet for 20 weeks and the aortic surface examined. While some foam cells were identified in these animals, there was no correlation with apoA-I genotype suggesting, while apoA-I may protect against atherogenesis, the lack of apoA-I by itself does not cause atherosclerosis.

1.4.4.3 *Expression of Human ApoA-I by Adenovirus-Mediated Gene Transfer in Mice*

The potential use of liver directed gene therapy to increase apoA-I and HDL plasma concentrations may prove to be an effective means by which to treat hypercholesterolemic and hypoalphalipoproteinemic patients. Thus, in 1994, Kopfler *et al.* described the first use of recombinant adenovirus to transiently express human apoA-I (hapoA-I Ad5) in BALB/c mice (268). Five days after intravenous infusion of hapoA-I Ad5, human apoA-I serum levels averaged 168 mg/dL while total and HDL cholesterol values increased 47% and 35%, respectively. They reported apoA-I expression declined to <10% of maximal plasma levels (day 4-6 post-injection) after 12 days while hepatic human apoA-I mRNA was undetectable at this time point. Following advances in adenovirus vector technology, Tsukamoto *et al.* reported in 1997 the use of second generation recombinant adenovirus able to mediate prolonged, high expression levels of human apoA-I in mice (269). ApoE deficient mice fed a chow diet, LDL receptor deficient and wild-type C57BL/6 mice fed a Western diet expressed peak apoA-I levels of 235, 324 and 276 mg/dL, respectively, following intravenous injection of this adenovirus. While human apoA-I was barely detectable 6 weeks post-injection in the apoE deficient mouse, the protein was still detectable after 8 months in LDL receptor deficient and wild-type C57BL/6 mice. Benoit *et al.* published in 1999 that injection of a human apoA-I recombinant adenovirus in wild-type C57BL/6 mice resulted in

a 40% increase in plasma HDL cholesterol levels while injection into apoA-I transgenic mice resulted in a 360% increase in plasma HDL cholesterol (270). They suggested this pronounced difference between mouse strains was due to an immune response mounted against human apoA-I in the wild-type C57BL/6 mouse. They subsequently injected this adenovirus into human apoA-I transgenic/apoE deficient mice prone to atherosclerosis. Over a 6 week period, adenovirus mediated expression of apoA-I inhibited the formation of fatty streak lesions by 56% as compared to non-injected controls. Furthermore, Tangirala *et al.* reported in 1999 that injection of a similar apoA-I adenovirus in LDL receptor deficient mice could induce regression of pre-existing fatty streaks (271).

1.5 Rationale and Specific Aims

The goal of this work is to characterize the structure-function relationships associated with the globular domain (residues 1-43) and the first class A helix (residues 44-65) of apoA-I.

Functional properties associated with these regions remain poorly characterized. An apoA-I mutant lacking residues 1-43 (Δ 1-43 apoA-I) was described previously (197,199,220) and suggested that the deleted amino-acids stabilized the lipid-free conformation of apoA-I. The X-ray crystal structure of this mutant suggests that apoA-I, when bound to HDL, wraps around the periphery of the particle perpendicular to the PL fatty-acyl chains (189). Previous work also demonstrates that deletion of these residues confers a 2-fold decrease in the ability of apoA-I to activate LCAT suggesting functional properties of this mutant may be moderately affected, as well. The importance of helix 1 (residues 44-65) for association of apoA-I with PL has been shown previously (212). Using synthetic peptides modeled after repeating 22-mer domains of apoA-I, Palgunachari and coworkers demonstrated that only

N- and C-terminal terminal peptides corresponding to a.a. 44-65 and 220-241 of apoA-I were able to clarify DMPC vesicles, implicating both the N- and C-terminus in PL binding. In addition, the characterization of an apoA-I deletion mutant lacking residues 1-65 suggests this protein has significantly less PL binding affinity relative to wild-type and Δ 1-43 apoA-I. However, the contributions of this helix to cholesterol efflux, LCAT activation and the *in vivo* maturation of HDL have not been fully characterized.

To investigate structure-function relationships associated with the N-terminus of apoA-I, we have taken a combined *in vitro* and *in vivo* approach. Firstly, histidine-tagged proteins were expressed in and purified from *E. coli*, corresponding to full-length wild-type apoA-I and 2 deletion mutants lacking residues 1-43 and residues 1-65. These recombinant proteins were compared with respect to cholesterol efflux, lipid-binding properties, ability to form reconstituted lipoproteins and activate LCAT. The goal of these studies is to ascertain whether the globular domain and/or the first class A helix contribute to these physical and functional properties of apoA-I. Secondly, recombinant adenoviruses were generated corresponding to wild-type apoA-I and similar N-terminal deletion mutants and injected into apoA-I deficient mice. The mutant proteins were compared to wild-type apoA-I expression levels in plasma, plasma lipid levels and HDL composition, size, electrophoretic migration and morphology. These experiments assess the importance of the globular domain and helix 1 to the *in vivo* maturation of HDL.

*CHAPTER 2: IN VITRO STRUCTURE-FUNCTION ANALYSIS OF THE
AMINO-TERMINUS OF APOLIPOPROTEIN A-I*

2.1 Summary

HDL transport cholesterol from peripheral tissues to the liver for excretion in the bile, a process known as reverse cholesterol transport (10). The primary protein constituent of HDL, apoA-I, is a 243 amino-acid plasma protein composed of 10 class A/Y amphipathic helices (a.a. 44-243) (reviewed in ref (79)) and a globular domain (a.a. 1-43) at the N-terminus containing a G* helix (a.a. 8-33) (188,272). Due to intrinsic differences in their physical properties, individual amphipathic helices are thought to differentially contribute to the physical and functional properties of apoA-I.

In this regard, physical-chemical properties associated with the globular domain and the first class A helix (a.a. 44-65) of apoA-I were studied. Recombinant histidine-tagged wild-type apoA-I (His-Wt apoA-I) and two N-terminal deletion mutants corresponding to the removal of residues 1-43 and 1-65 (referred to as His- Δ 1-43 and His- Δ 1-65 apoA-I) were expressed in *E. coli* and purified by affinity chromatography.

Cell association and cholesterol efflux from J774 macrophage to His-Wt, His- Δ 1-43 and His- Δ 1-65 apoA-I were similar while efflux to an apoA-I mutant lacking residues 210-243 was significantly reduced. This suggests the extreme amino-terminus is not crucial for cholesterol efflux mediated by apoA-I. Native lipid-binding properties were disrupted for both His- Δ 1-43 and, more markedly, His- Δ 1-65 apoA-I relative to His-Wt apoA-I as determined by a reduced rate of clearance of DMPC liposome turbidity. Reconstituted discoidal lipoproteins were prepared in order to compare the stability and functional properties of His-Wt apoA-I to the N-terminal mutants. Reconstituted lipoproteins containing the apoA-I deletion mutants exhibited similar stabilities in the presence of guanidine hydrochloride as compared to those containing His-Wt apoA-I. Therefore,

deletions in the amino-terminus do not appreciably affect the stability of apoA-I in these synthetic lipoprotein particles. Finally, LCAT activation was reduced to 50% and 34% (decrease in V_{max}) for His- Δ 1-43 and His- Δ 1-65 apoA-I relative to His-Wt apoA-I suggesting the amino-terminus is involved in LCAT activation.

These studies suggest the globular domain (a.a. 1-43) and the first class A helix (a.a. 44-65) are not involved in cholesterol efflux but do affect the native lipid-binding properties of apoA-I. Furthermore, the extreme amino-terminus of apoA-I, encompassing both the globular domain and helix 1 are critical LCAT activating domains.

2.2 Materials and Methods

2.2.1 Construction of the cDNA for His-ApoA-I Expression

Histidine (His)-tagged wild-type apoA-I (His-Wt apoA-I) was generated in our laboratory previously (273) and the deletion mutant lacking residues 1-65 (His- Δ 1-65 apoA-I) was acquired from Drs. Christie G. Brouillette and Jeffrey A. Engler (199). The apoA-I mutant in which residues 1-43 were deleted (His- Δ 1-43 apoA-I) was generated by deletion mutagenesis using the Excite mutagenesis kit from Stratagene and the oligonucleotides: 5'-PCATATGGTGATGGTGATGGTGCG-3' (upstream) and 5'-CTAAAGCTCCTTGACAACCTGGGACAGCG-3' (downstream). The apoA-I mutant lacking residues 210-243 (His- Δ 210-243 apoA-I) was generated by similar methods using the following oligonucleotides: 5'-GGGCTTGGCCTTCTCGCTGAGCG-3' (upstream) and 5'-PTGAGGCGCCCGCCGCCCCCTTC-3' (downstream).

Figure 2-1: Secondary Structural Elements of the Histidine-Tagged ApoA-I

The positioning of the class A (blue), Y (red) and G* (green) helices in His-Wt apoA-I is shown. Deletion of residues 1-43 removes the globular domain consisting of the G* helix (a.a. 8-33) and the unordered residues 1-7 and 33-44. Deletion of residues 1-65 results in the successive removal of the 1st class A helix (a.a. 44-65).

2.2.2 · Cell Culture

J774 mouse peritoneal macrophages were maintained between passages in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% (vol/vol) fetal bovine serum (FBS), 100 U/mL penicillin, 100 U/mL streptomycin sulfate and 2 mM L-glutamine. Cell culture plasticware and reagents were purchased from Falcon, Gibco BRL and Sigma.

2.2.3 Purification of Histidine-Tagged ApoA-I

All recombinant His-apoA-I proteins were expressed under the control of the T₇ promoter and purified in BL21 DE3 *E. coli* as described previously (273) with some minor changes (274). His-Wt and His-Δ1-43 apoA-I were subcloned into the pET 3a expression vector while His-Δ1-65 apoA-I subcloned into the pGEMX expression vector (Invitrogen). For protein expression, *E. coli* were newly transformed with 1 ng of the apoA-I-containing constructs. Overnight LB precultures, grown for 12 h at 37°C in a bacterial shaker at 200 rpm in 100 μg/mL ampicillin, were used to inoculate 1 L flasks of LB growth medium. A 1/100 (v/v) inoculum was used and the cultures grown to an OD₆₀₀ of 0.45. Protein expression was induced by adding 1/100 (v/v) of 0.1 M isopropyl-β-D-thiogalactopyranoside (IPTG), followed by a further 2 h of incubation under the above conditions following. Cells were harvested by centrifugation and frozen at -20°C. The pellet was later resuspended in buffer A (100 mM Na₂HPO₄, 1 mM PMSF and 6 M GdnHCl, pH 8.0). The solution was sonicated on ice and the bacterial debris removed by centrifugation for 1 h at 11 000×g. Nucleic acids were removed by incubation of the supernatant in streptomycin sulfate (10 mL of 10% solution per gram protein) at 4°C for 1 h. Following a

subsequent centrifugation, the supernatant was applied to a nitrilotriacetic acid-agarose (Qiagen) column equilibrated with buffer A. After application, the column was washed with buffer A and then weakly bound proteins were eluted by washing with 100 mM phosphate/citrate, 6 M GdnHCl, pH 6.0. The recombinant, histidine-tagged apoA-I proteins were eluted with the latter buffer adjusted to pH 5.0. Collected fractions were neutralized by addition of 1 M NaOH and supplemented with 0.1 M EDTA and PMSF. The fractions containing the greatest concentration of protein, as determined by 12% SDS-PAGE, were pooled and dialyzed against 5 mM NH_4HCO_3 , 1 mM EDTA, 0.02% NaN_3 and lyophilized. Proteins were stored at -20°C . For experiments, the lyophilized protein was solubilized in 6 M GdnHCl, pH 8.0 and dialyzed against phosphate-buffered saline (PBS).

2.2.4 *Competitive Cell Surface Association*

Cholesterol-loaded J774 macrophage were seeded in 12-well plates at a density of 2×10^4 cells/well and grown for 48 h before cholesterol loading. Washed cells were incubated with 1 mL of Dulbecco's minimal essential medium (DMEM) containing 1% FBS and 75 μg of acetylated LDL (AcLDL) for 48 h. Cells were then washed with DMEM containing 0.2% bovine serum albumin (BSA) and incubated in DMEM containing 0.2% BSA with or without 0.3 mM 8-bromoadenosine 3':5'-cyclic monophosphate (cAMP) (Sigma) for 12 h. Washed cells were incubated with 1×10^6 cpm of iodinated His-Wt apoA-I (^{125}I -His-Wt apoA-I) in the presence of nonlabeled His-Wt, His- $\Delta 1$ -43, His- $\Delta 1$ -65 and His- $\Delta 210$ -243 apoA-I in the following molar ratios of labeled to nonlabeled apoA-I: 1:0, 1:1, 1:3, 1:10 and 1:50. After 2 h, the cells were solubilized in 0.5 N NaOH and counted for gamma radioactivity. Radioactivity was normalized to cell protein content assessed by the method of Markwell and Lowry (275).

2.2.5 Cholesterol Efflux

Efflux assays were performed with cholesterol loaded J774 macrophage as described by Sakr *et al.* (276) with several modifications. Cells were seeded in 12-well plates at a density of 2×10^4 cells/well and grown for 48 h before cholesterol loading. Cells were cholesterol loaded for 48 h in 1 mL of DMEM containing 1% FBS and [1α , 2α - ^3H] cholesterol (NEN Life Science Products) (15 $\mu\text{Ci}/\text{mL}$ final concentration), which had been pre-incubated for 30 min at 37°C with AcLDL (75 $\mu\text{g}/\text{mL}$ final concentration). Subsequently, cells were washed 3 \times in DMEM containing 0.2% BSA and incubated in DMEM containing 0.2% BSA with or without cAMP for 12 h. Cells were then washed 3 \times in DMEM containing 0.2% BSA. For the efflux assay, cells were incubated for 0, 2, 6 and 24 h in 1 mL of DMEM containing 0.2% BSA with or without 0.3 mM cAMP containing 50 μg His-Wt apoA-I or equivalent moles of each apoA-I deletion mutant. At the appropriate time point, media samples were removed and centrifuged at $1\ 000\times\text{g}$ to remove floating cells. Cells were solubilized in 1 mL of 0.5 N NaOH and assayed for cell protein content by the method of Markwell and Lowry (275). The radioactivity in all samples was determined by liquid scintillation counting. Cholesterol efflux was calculated as the percentage of initial cell radioactivity associated with the media as a function of time. Values were corrected at each time point for the efflux of cholesterol to medium not containing apoA-I. The percentage stimulation of cholesterol efflux in response to cAMP treatment was calculated according to the following equation: $(\text{efflux from J774 cells treated with cAMP} - \text{efflux from J774 cells in the absence of cAMP}) / (\text{efflux from J774 cells in the absence of cAMP}) \times 100\%$ (277).

2.2.6 DMPC Clearance

The ability of apoA-I to clear a solution of dimyristoylphosphatidylcholine (DMPC) at its transition temperature (23.9°C) was assessed as initially described by Pownall *et al.* (278). Briefly, DMPC solubilized in chloroform was dried under nitrogen and solubilized above its transition temperature in tris-buffered saline (TBS), pH 8.0. A DMPC to apoA-I ratio of 50:1 was used and the reaction followed at 23.9°C by measuring the absorbance at 325 nm for 30 min. A decrease in absorbance is associated with the solubilization of the liposomes by apoA-I and the formation of discoidal complexes, the rate of which is proportional to the affinity of apoA-I for phospholipid.

2.2.7 Preparation of Reconstituted Lp2A-I

Reconstituted discoidal lipoproteins containing 2 molecules of apoA-I (Lp2A-I) were prepared by cholate dispersion/Bio-Bead removal protocol using initial molar ratios of 80:10:1 of 1-palmitoyl-2-oleoyl-phosphatidylcholine (PL) (Avanti Polar Lipids), FC (Sigma) and His-apoA-I, respectively, as described elsewhere (279). Particle size and homogeneity were confirmed by 4-20% non-denaturing gradient gel electrophoresis (PAGE). Each particle contained 2 molecules of apoA-I as determined by cross-linking with dimethylsuberimidate, according to an established protocol (280). Enzymatic kits were used to determine the final PL (Wako Chemicals) and FC (Roche Diagnostics) concentrations. The apoA-I content was measured according to the method of Markwell and Lowry (275) using a BSA standard. The stability of the Lp2A-Is was assessed by circular dichroism spectroscopy using a Jasco J41A spectropolarimeter and an established protocol (211). The change in molar ellipticity was determined at 222 nm with increasing concentrations of guanidine hydrochloride to calculate the standard free energy of denaturation (ΔG_D°).

2.2.8 LCAT Assay

Human LCAT was purified as described previously (281). Lp2A-Is were prepared containing [³H] cholesterol and His-Wt, His-Δ1-43 or His-Δ1-65 apoA-I. Two distinct types of experiments were performed. The time course assay was performed as described previously (274) by incubating 3.5 U of LCAT with Lp2A-I for 0, 0.5, 1, 2, 3, 4 and 5 h at 37°C at a final apoA-I concentration of 2.14 μM. In the second experiment, the rate constants V_{max} and apparent K_m ($appK_m$) were determined by incubating Lp2A-Is at the concentrations indicated (expressed in μM apoA-I) for 10 min at 37°C. In both cases, the reactions were terminated by the addition of 2 mL of ethanol and minimal substrate conversion was determined (282). The values indicated are the mean (\pm standard error) of triplicate results and are representative of 2 independent experiments. One unit of LCAT is defined as the amount of enzyme required to convert 1 nmol of FC to CE per hour using a standard His-Wt Lp2A-I at a final concentration of 2.0 μM.

2.2.9 Electrophoresis

SDS-PAGE was performed using 12% acrylamide pre-cast Novex gels (Invitrogen) according to the manufacturer's specifications. Non-denaturing PAGE was done using 4-20% acrylamide pre-cast Novex gels and samples were separated for 2000V×h. Pre β - and α -HDL were separated by agarose gel electrophoresis (Beckman Lipogel) followed by neutral lipid staining (Beckman) or Western blotting using a biotinylated anti-apoA-I monoclonal antibody (A44). Samples were separated for 30 min at 100V.

2.2.10 *Western Blotting*

Samples separated by 12% SDS-PAGE were transferred to nitrocellulose at 125 V for 1 h while those separated by 4-20% PAGE were transferred at 125 V for 2 h. Membranes were probed either with the biotinylated A44 monoclonal antibody directed against the central domain of apoA-I (a.a 149-186), an anti-human apoA-I polyclonal from sheep (Roche Molecular Biochemicals) or an anti-mouse apoE polyclonal from rabbit (Biodesign International). Proteins were visualized by chemiluminescence following incubation with either streptavidin (Amersham Life Science), donkey anti-sheep IgG (Sigma) or donkey anti-rabbit IgG (Amersham Life Science) coupled to HRP.

2.3 Results

2.3.1 Expression of Histidine-Tagged Wild-Type and Mutant ApoA-I

In order to address the contribution of the extreme amino-terminus to various physico-chemical properties of apoA-I, His-Wt apoA-I and 2 deletion mutants, corresponding to the removal of residues 1-43 and 1-65, with N-terminal histidine tags were expressed and purified from *E.coli* (Fig. 2-2). All 3 proteins were expressed at high levels and appeared to reach peak expression at similar time-points following the addition of IPTG (2 h). The apparent molecular weight as determined by 12% SDS-PAGE corresponded with the expected size of the histidine-tagged proteins, 29.5 kDa, 24.6 kDa and 22.0 kDa for His-Wt, His- Δ 1-43 and His- Δ 1-65 apoA-I, respectively. These proteins all efficiently bound the

Figure 2-2: *E. coli* Expression of Wild-Type and Mutant Histidine-Tagged ApoA-I

Overnight precultures of *E. coli* transformed with the His-Wt, His- Δ 1-43 and His- Δ 1-65 were used to inoculate 1 L flasks of LB growth medium for protein expression. The cultures were grown to an OD_{600} of 0.45 and subsequently induced by the addition of IPTG. Cultures were incubated for a further 2 h at 37°C in a bacterial shaker at 150 rpm and centrifuged to collect a bacterial pellet. *E. coli* cell lysates prior to IPTG induction (lanes 2, 5 and 8), after induction and prior to centrifugation (lanes 3, 6 and 9) and after purification (see *Materials & Methods*) (lanes 4, 7 and 10) are shown for His-Wt (lanes 2, 3 and 4), His- Δ 1-43 (lanes 5, 6 and 7) and His- Δ 1-65 (lanes 8, 9 and 10) following separation by 12% SDS-PAGE and Coomassie blue staining.

NTA resin and were recovered following elution at pH 5.0 to similar extents. After removal of GdnHCl by dialysis, His- Δ 1-43, but not His-Wt or His- Δ 1-65 apoA-I, tended to aggregate and precipitate from solution resulting in a lower yield of this protein. The tendency of this mutant to aggregate in solution has been documented previously (272) and may be due to the effect of this particular mutation on the integrity of the lipid-free structure of apoA-I. Inclusion of a small amount of cholic acid in the dialysis buffer significantly increased the yield of this mutant and was subsequently removed by incubation with a hydrophobic, polystyrene absorbent (Bio-Beads).

2.3.2 *Effect of Amino-Terminal Deletions on Macrophage Cell Surface Association*

We first evaluated the effect of these deletions on the ability of apoA-I to bind macrophage at 37°C. Previous work indicates the binding of apoA-I mutants to macrophage directly correlates with their ability to elicit cellular cholesterol efflux. Thus to emulate the conditions used for cholesterol efflux, J774 macrophages were cholesterol-loaded using AcLDL as described in *Materials & Methods*. In order to compare the relative binding efficiencies of His-Wt, His- Δ 1-43 and His- Δ 1-65, a competitive cell association assay was used. Iodinated His-Wt apoA-I (1 000 000 cpm) (referred to as 125 I-His-Wt apoA-I) was added to the cell culture medium in the absence or presence of non-labeled apoA-I competitor. Non-labelled His-Wt, His- Δ 1-43, His- Δ 1-65 and His- Δ 210-243 were added at molar ratios of 1:0, 1:1, 1:3, 1:10 and 1:50 for 125 I-His-Wt apoA-I to competitor, respectively. After 2 h of incubation, the culture medium was removed and the cell-associated radioactivity was determined. In addition, cells were pretreated for 12 h with culture medium containing 0.3 mM cAMP, which increases the expression of ABCA1 (98), and significantly increased the specific association of 125 I-His-Wt apoA-I with these cells relative

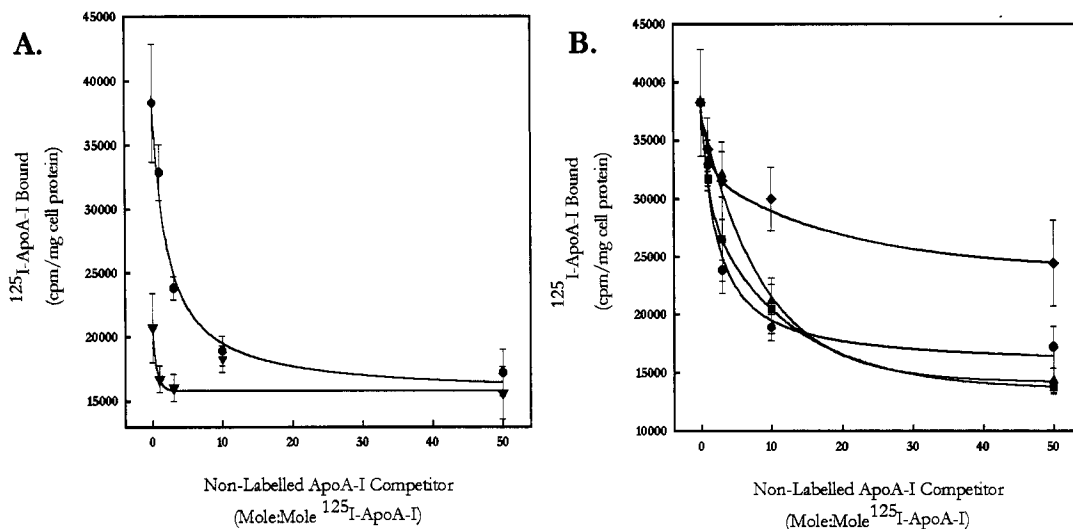

Figure 2-3: Effect of ApoA-I Amino-Terminal Deletions on J774 Macrophage Cell Association

(A) The binding of ^{125}I -His-Wt apoA-I to cholesterol-loaded J774 macrophage, either pretreated (●) or not pretreated (▼) with 0.3 mM cAMP, at 37°C and in the presence of non-labeled His-Wt apoA-I at varying molar ratios is shown.

(B) Cells were pretreated with 0.3 mM cAMP. The abilities of His-Wt (●), His-Δ1-43 (▲), His-Δ1-65 (■) and His-Δ210-243 (◆) apoA-I to compete for the binding of ^{125}I -His-Wt apoA-I are shown.

to cells not pretreated with cAMP (Fig. 2-3A). I found that both His-Δ1-43 and His-Δ1-65 apoA-I were as effective as His-Wt apoA-I in competing for the binding of ^{125}I -His-Wt apoA-I, while His-Δ210-243 apoA-I poorly competed (Fig. 2-3B). This work suggested that deletion of the globular domain and helix 1 had no effect on the ability of apoA-I to associate with macrophage, which is primarily dependent upon the presence of the carboxy-terminus.

2.3.2 Cholesterol Efflux from J774 Macrophage to His-Wt, His-Δ1-43, His-Δ1-65 and His-Δ210-243 ApoA-I

His-Wt, His- Δ1-43, His- Δ1-65 and His- Δ210-243 apoA-I were used to evaluate the potential contribution of the N-terminus of apoA-I to cellular cholesterol efflux. Cells were

Figure 2-4: Effect of Amino-Terminal Deletions on Cholesterol Efflux to ApoA-I

Cholesterol loaded J774 macrophage were incubated for 12 h in DMEM containing 0.2% BSA with (A) or without (B) 0.3 mM cAMP. This medium was replaced with 1 mL of DMEM containing 0.2% BSA and 50 µg of His-Wt (●) apoA-I or equivalent moles of His-Δ1-43 (▲), His-Δ1-65 (■) and His-Δ210-243 (◆) apoA-I and incubated for 0, 2, 6 and 24 h. At each time point, the medium was removed and radioactivity was determined by liquid scintillation counting.

first cholesterol loaded for 48 h with AcLDL and subsequently equilibrated for 12 h in either the absence or presence of 0.3 mM cAMP. Medium containing 50 µg of His-Wt apoA-I or equivalent moles of His- Δ1-43, His- Δ1-65 and His- Δ210-243 apoA-I were then added and the efflux to each acceptor determined over time. In the absence of cAMP (Fig. 2-4A, Table 2-1), efflux to His-Δ1-43 and His-Δ1-65 apoA-I was slightly, but significantly ($p < 0.01$, student's t-test), reduced relative to His-Wt apoA-I while efflux to His- Δ210-243 apoA-I was greatly reduced (2.2-fold) ($p < 0.01$, student's t-test) by comparison. In the presence of cAMP (Fig. 2-4B, Table 2-1), efflux to His- Δ1-43 and His- Δ1-65 apoA-I was not statistically different from His-Wt apoA-I. In contrast, efflux in the presence of cAMP for His- Δ210-243 apoA-I was significantly reduced ($p < 0.01$, student's t-test) relative to His-Wt apoA-I and the two N-terminal mutants (1.5-fold).

Table 2-1: The Rate of Cholesterol Efflux from J774 Macrophage to His Wt, His-Δ1-43, His-Δ1-65 and His-Δ210-243 ApoA-I

	Slope (% Cell Cholesterol/h)	R ²	Stimulation with cAMP (%)
His-Wt ApoA-I			
-cAMP	0.97 ± 0.02	0.99 ± 0.01	87 ± 5
+cAMP	1.83 ± 0.06	0.99 ± 0.01	
His-Δ1-43 ApoA-I			
-cAMP	0.88 ± 0.02 ^a	0.99 ± 0.01	78 ± 3
+cAMP	1.66 ± 0.05	0.99 ± 0.01	
His-Δ1-65 ApoA-I			
-cAMP	0.86 ± 0.02 ^a	1.00 ± 0.01	91 ± 1
+cAMP	1.77 ± 0.01	1.00 ± 0.01	
His-Δ210-243 ApoA-I			
-cAMP	0.45 ± 0.03 ^a	0.99 ± 0.01	73 ± 1
+cAMP	1.19 ± 0.02 ^a	0.99 ± 0.02	

Cholesterol efflux assays using J774 macrophage were performed as described in *Materials & Methods*. After cholesterol loading, cells were equilibrated for 12 h in the absence and in the presence of 0.3 mM cAMP. The slope represents the rate of cholesterol efflux to each apoA-I protein expressed as the percentage of initial cell ³H-cholesterol label effluxed to the media per hour of incubation. Values represent the mean ± SE.

^aValues statistically different (p<0.01) (student's t test) relative to His-Wt apoA-I

2.3.4 Effect of Amino-Terminal Deletions on Phospholipid Binding Affinity

The relative abilities of His-Wt, His-Δ1-43, His-Δ1-65 and His-Δ210-243 apoA-I to clarify a solution of DMPC liposomes was determined to evaluate the effect of these mutations on apoA-I PL binding. In this assay, the various apoA-Is were added to a solution of DMPC, prepared as described in *Materials and Methods*, at a 50:1 molar ratio (DMPC to apoA-I, respectively). ApoA-I solubilizes the DMPC liposomes forming discoidal HDL complexes and concomitantly reduces the turbidity of the solution, a property monitored by the decrease in absorbance at 325 nm. Relative to His-Wt apoA-I, both His-Δ1-43 and, more markedly, His-Δ1-65 exhibited a reduced rate of DMPC clearance suggesting that the initial rate of PL association is significantly affected by both the deletion

Figure 2-5: Rate of DMPC Clearance Associated Wild-Type and Mutant ApoA-Is

50 μg of His-Wt (●) apoA-I or equivalent moles of His- Δ 1-43 (▲), His- Δ 1-65 (■) and His- Δ 210-243 (◆) apoA-I was added to a solution of DMPC liposomes and the absorbance monitored at 325 nm for 30 min at 23.9°C.

of residues 1-43 and the additional deletion of residues 44-65 (Fig. 2-5). The deletion of residues 1-65 disrupted the rate of DMPC clearance to a degree comparable to that of His- Δ 210-243 apoA-I, a mutation which has previously been shown to significantly affect native lipid-binding properties of apoA-I (213).

2.3.5 Preparation of Reconstituted Lipoproteins Containing Wild-Type ApoA-I and the Amino-Terminal Deletion Mutants

Reconstituted, discoidal lipoproteins containing 2 molecules of apoA-I were prepared using the sodium cholate dispersion and Biobead removal method described by Sparks *et al.* (211) using His-Wt, His- Δ 1-43 and His- Δ 1-65 apoA-I. Initial ratios of 80:10:1 for POPC, FC and His-apoA-I, respectively, were used. The relative compositions, expressed as the number of molecules of PL and FC per molecule of apoA-I, and particle size were then determined (Fig. 2-6). Lp2A-Is reconstituted with His- Δ 1-43 apoA-I

Figure 2-6: Size and Stability of Lp2A-Is Containing His-Wt, His- Δ 1-43 and His- Δ 1-65 ApoA-I

Lp2A-Is were prepared by cholate dispersion and Biobead removal containing 80:10:1 of PL, FC and His-apoA-I. (A) A non-denaturing 4-20% gradient gel separation of Lp2A-Is containing His-Wt (lane 3), His- Δ 1-43 (lane 4) and His- Δ 1-65 (lane 5) is shown. Molecular weight markers (lane 1) and human HDL (lane 2) are shown for reference. (B) The thermodynamic stability of the Lp2A-Is were compared by far UV circular dichroism spectroscopy (see *Materials and Methods*). Lp2A-Is containing His-Wt (\bullet), His- Δ 1-43 (\blacktriangle) and His- Δ 1-65 (\blacksquare) were incubated with varying concentrations of the chaotropic agent guanidine hydrochloride for 48 h. Subsequently, the presence of apoA-I secondary structure was ascertained by the absorbance at 222 nm.

contained slightly fewer molecules of PL (58.7 ± 0.9) and FC (7.5 ± 0.2) per molecule of apoA-I as compared to both His-Wt (62.7 ± 5.9 mol PL/mol apoA-I, 8.9 ± 0.3 mol FC/mol apoA-I) and His- Δ 1-65 (64.7 ± 5.8 mol PL/mol apoA-I, 8.7 ± 0.6 mol FC/mol apoA-I) apoA-I. Furthermore, the stability of the reconstituted lipoproteins containing His-Wt, His- Δ 1-43 and His- Δ 1-65 apoA-I was assessed by far UV circular dichroism spectroscopy. Fig. 2-6B represents the denaturation curve of each lipoprotein expressed as the fraction of apoA-I secondary structure unfolded in the presence of guanidine hydrochloride. The

midpoint of the denaturation curve was used to calculate the standard free energy of denaturation (ΔG_D°) and was very similar for His-Wt (2.81 ± 0.04 M), His- $\Delta 1-43$ (2.53 ± 0.06 M) and His- $\Delta 1-65$ (3.01 ± 0.09 M) apoA-I containing Lp2A-I.

2.3.6 Effect of ApoA-I Amino-Terminal Deletions on LCAT Activation

Subsequently, we assessed the ability of reconstituted lipoproteins containing His-Wt, His- $\Delta 1-43$ and His- $\Delta 1-65$ apoA-I to stimulate LCAT mediated cholesterol esterification *in vitro*. Reconstituted, discoidal lipoproteins (Lp2A-I) were prepared with initial molar ratios of 80:10:1 of PL, FC and His-apoA-I, respectively. During a 5 h time course experiment (Fig. 2-7A), the formation of CE was reduced to 50% and 48% for His-

Figure 2-7: Effect of ApoA-I Amino-Terminal Deletions on LCAT Activation

Reconstituted, discoidal Lp2A-I s were prepared as described in the *Materials & Methods* containing ^3H -cholesterol. Panel A represents a time-course assay in which these lipoprotein substrates were incubated with 3.5 U of purified human LCAT and the yield of ^3H -cholesteryl ester was determined at various time-points after TLC separation and liquid scintillation counting. In Panel B, the substrates were incubated at various concentrations (expressed as μM apoA-I) with 1.25 U of purified human LCAT for 10 min. In both panels the plots representing Lp2A-I s containing His-Wt (●), His- $\Delta 1-43$ (▲) and His- $\Delta 1-65$ (■) are shown.

$\Delta 1-43$ and His- $\Delta 1-65$ Lp2A-I, respectively, relative to His-Wt Lp2A-I ($p < 0.05$, student's t-test). Analysis of the Michaelis-Menten kinetics (Fig. 2-7B) indicated that the V_{max} for His- $\Delta 1-43$ and His- $\Delta 1-65$ Lp2A-I was reduced to 50% and 34%, respectively, relative to His-Wt Lp2A-I ($p < 0.05$, student's t-test) (Table 2-2).

Table 2-2: LCAT enzyme kinetics associated with His-Wt, His- $\Delta 1-43$ and His- $\Delta 1-65$ Lp2A-I substrates. V_{max} and apparent K_m values were determined by Lineweaver-Burk analysis.

	V_{max} (nmol CE/h/unit LCAT ^a)	App K_m ^b (μM)
His-Wt ApoA-I	3.14 \pm 0.37	1.62 \pm 0.20
His- $\Delta 1-43$ ApoA-I	1.56 \pm 0.20 ^c	3.02 \pm 0.34 ^c
His- $\Delta 1-65$ ApoA-I	1.07 \pm 0.18 ^c	0.90 \pm 0.34

LCAT assays were performed as described in *Materials & Methods* using reconstituted Lp2A-I of initial molar ratios 80:10:1 of PL, FC and apoA-I, respectively. V_{max} and apparent K_m (app K_m) were determined by Lineweaver-Burk analysis. Values represent the mean \pm SE.

^aUnit of LCAT activity was defined as the amount of enzyme required to convert 1 nmol of FC to CE using a standard Lp2A-I containing His-Wt apoA-I at 2 μM .

^bapp K_m for apoA-I

^cValues which are statistically significant to $p < 0.05$ (student's t-test) relative to His-Wt apoA-I.

2.4 Discussion

Analysis of apoA-I structure-function relationships is important in understanding HDL metabolism and reverse cholesterol transport. Here the extreme amino-terminus composed of the globular domain (a.a. 1-43) and the first class A amphipathic helix (a.a. 44-65) and their contributions to lipid-binding, cholesterol efflux and LCAT activation were addressed.

His- Δ 1-43 and His- Δ 1-65 apoA-I were expressed at levels comparable to His-Wt apoA-I in *E. coli*. Some apoA-I mutants used in our laboratory previously are expressed at much lower levels but it is not clear why this is the case. The N-terminal deletion mutants might be expected to express at lower levels as these deletions have been shown previously to significantly disrupt the lipid-free structure of apoA-I. This could have rendered these mutants more susceptible to proteolysis in the bacterium, however, there is no indication this was the case. After the removal of GdnHCl, a significant portion of His- Δ 1-43 apoA-I was found to aggregate and precipitate from solution, a property of this mutant shown previously, while His- Δ 1-65 and His-Wt apoA-I did not. This may be due to the role of the globular domain in maintaining the lipid-free structure of apoA-I. The transition from lipid-free to lipid-bound structure is thought to involve the exposure of the hydrophobic faces of the helices in apoA-I, previously sequestered within the helix bundle for lipid-binding (reviewed in ref (79)). In solution, a disruption of the helix bundle, exposing the hydrophobic faces, may generate hydrophobic pockets where apoA-I self-associates through hydrophobic interactions. The lipid-free structure of His- Δ 1-65 apoA-I has been shown previously to be significantly different than His- Δ 1-43 apoA-I and may be such that self-association is not significantly altered by this larger deletion. Thus, we can tentatively

conclude that the G* helix (a.a 8-33) serves to mask the hydrophobic face of helix 1 (a.a. 44-65) in the lipid-free form of apoA-I.

The importance of the C-terminus (a.a. 187-243) of apoA-I in both PL binding and cholesterol efflux has been shown previously (213,237,283), suggesting these 2 properties may be related. In order to determine if either the N-terminal globular domain or helix 1 are involved in cell binding or cellular cholesterol efflux, I compared these properties using cholesterol loaded J774 macrophages and lipid-free His-Wt, His- Δ 1-43, His- Δ 1-65 and His- Δ 210-243 apoA-I. Deletion of the globular domain and helix 1 did not impair the ability of apoA-I to associate with macrophage at 37°C (Fig. 2-3B) or elicit cholesterol efflux (Fig. 2-4, Table 2-1) to an appreciable extent. Interestingly, these observations are inconsistent with studies addressing the ability of individual apoA-I synthetic peptides to elicit cholesterol efflux from human skin fibroblasts (249). From a panel of synthetic peptides modeled after apoA-I helices, only those corresponding to a.a. 44-65, 44-87 and 209-241 were shown to stimulate cholesterol efflux, suggesting a.a. 44-65 are important for this property. However, it is difficult to compare individual helical peptides to apoA-I mutants containing many more amphipathic α -helices. Furthermore, comparison of efflux to apoA-I mutants from macrophage and fibroblast cell lines has yielded conflicting results previously (213,249), suggesting that extrapolation from one cell type to another is not necessarily warranted. Nonetheless, the results here show that the C-terminus of apoA-I is more important than the N-terminus in promoting cholesterol efflux from macrophage.

The amino-terminal deletions were then compared to His-Wt apoA-I with respect to their ability to bind to DMPC liposomes and form reconstituted, discoidal lipoproteins. Both the deletion of the globular domain and the subsequent deletion of helix 1 were associated with significant reductions in the ability of apoA-I to bind PL (Fig. 2-5). The

importance of residues 44-65 was suggested initially by Palgunachari *et al* (212). They demonstrated that from a panel of synthetic peptides modeled after the exon 4 encoded 22-mers of apoA-I (residues 44-243) that only those corresponding to residues 44-65 and 220-241 had significant lipid binding affinity. While initial studies by Segrest *et al.* suggested little PL binding could be attributed to the globular domain of apoA-I (reviewed in ref (188)), Mishra *et al.* showed that a synthetic peptide modeled after residues 1-33 of apoA-I had significant affinity for PL (221). This suggests the globular domain may be an important region for lipid-binding, as the removal of residues 1-43 significantly reduced the rate at which apoA-I binds to DMPC liposomes.

While the initial rate of PL binding was reduced by deletion of the amino-terminus of apoA-I, the structure and stability of reconstituted lipoproteins were minimally affected. The His- Δ 1-43 apoA-I mutant was associated with slightly less PL and FC and correlated with a smaller particle size relative to both His-Wt and His- Δ 1-65 apoA-I (Fig. 2-6A). This may have been due to the self-aggregation observed for this mutant in solution, which could have altered the association with PL and FC to form discoidal lipoproteins. This did not appear to have a significant effect on the stability of the reconstituted lipoprotein, which exhibited a similar ΔG_D° to Lp2A-Is containing His-Wt and His- Δ 1-65 apoA-I (Fig. 2-6B).

Subsequently, we used these reconstituted lipoproteins to address the contribution of the N-terminus to LCAT activation. Deletion of the globular domain of apoA-I has been shown previously to confer a 2-fold reduction in the capacity of apoA-I to activate LCAT (197), however, the role of helix 1 was previously unclear. The effect conferred by the deletion of residues 1-65 of apoA-I was assayed previously using an egg PC vesicular assay (199), however, this study could not differentiate between decreased PL binding and a direct effect of this mutation on LCAT activation. Here, we prepared reconstituted Lp2A-Is with

His-Wt, His- Δ 1-43, and His- Δ 1-65 apoA-I that were of similar composition and stability, properties that have been shown to affect LCAT activation independently (284). We observed that His- Δ 1-43 and His- Δ 1-65 apoA-I were associated with 50% and 34% decreases in LCAT activation, respectively, relative to His-Wt apoA-I (Fig. 2-7, Table 2-2). The observation that these deletions affected LCAT activation is intriguing since this property is generally associated with class A helices of the central domain, in particular helix 6 (219,258,259). Recent work suggests that a cluster of 3 Arg residues at the interface of the hydrophilic and hydrophobic faces in helix 6 contributes to a specific locale of positive surface potential that may stimulate LCAT activity (260). Site-specific mutagenesis of these residues conferred 11-12-fold reductions (decrease in V_{max}) in LCAT activation without affecting other physical properties of apoA-I. The current study supports previous work implicating the globular domain of apoA-I in LCAT activation and further suggests that helix 1 may be an important domain for this property, as well.

In summary, this work suggests that although the amino-terminus of apoA-I does contribute to the native lipid-binding properties of apoA-I, it is not involved in cholesterol efflux from macrophage. However, the N-terminus of apoA-I does appear to act as a critical LCAT activating domain.

*CHAPTER 3: CONTRIBUTION OF THE AMINO-TERMINUS OF
APOLIPOPROTEIN A-I TO THE IN VIVO MATURATION OF HDL*

3.1 Summary

Nascent HDL are secreted by hepatocytes, liberated from chylomicrons during TG lipolysis, and are derived from HDL remodeling by hepatic lipase and CETP (reviewed in Section 1.3.3.1). The importance of PLTP in the lipidation of this nascent HDL pool has recently emerged since PLTP deficient mice exhibit defective PL transfer from TG-rich lipoproteins to HDL, reduced HDL levels and increased HDL catabolism (285). Efflux of cholesterol and PL from cells provide nascent HDL with lipid constituents. This step is important for steady-state concentrations of HDL and may be rate-limiting as heterozygous mutations in ABCA1 can cause familial HDL deficiency (118). The combined actions of PLTP and ABCA1 generate larger, discoidal pre β_2 and pre β_3 -HDL from the nascent HDL pool. These are converted to spherical α -migrating HDL by the actions of LCAT as newly synthesized CE partitions to the HDL core.

To further define the role of the amino-terminus of apoA-I in HDL maturation, we constructed recombinant adenoviruses containing Wt apoA-I and two similar mutants with deletions of residues 7-43 and 7-65 (referred to as $\Delta 7$ -43 and $\Delta 7$ -65 apoA-I). Residues 1-6 were not removed in these mutants to allow proper cleavage of the pro-sequence *in vivo*. Following injection of these adenoviruses into apoA-I deficient mice, both $\Delta 7$ -43 and $\Delta 7$ -65 apoA-I were expressed at approximately 4-fold lower levels than Wt apoA-I. A 4-fold greater adenovirus dose for both $\Delta 7$ -43 and $\Delta 7$ -65 apoA-I Ad5 resulted in plasma levels 4 days post-injection of these mutants similar to Wt apoA-I. HDL associated with each of these mutants accumulated less CE than Wt apoA-I HDL. Wt and $\Delta 7$ -43 apoA-I formed predominantly α -migrating and spherical HDL whereas only $\Delta 7$ -65 apoA-I formed pre β -

HDL of discoidal morphology. This demonstrates that the N-terminus of apoA-I, in particular the first class A helix (a.a. 44-65), is important for the *in vivo* maturation of HDL.

3.2 Materials and Methods

3.2.1 Production of 1st Generation Recombinant Adenoviruses

The cDNAs for apoA-I deletion mutants lacking residues 7-43 (Δ 7-43 apoA-I) and residues 7-65 (Δ 7-65 apoA-I) were subcloned into the pCA13 vector (Microbix Biosystems Inc.). Wt apoA-I Ad5 was generated in our laboratory previously (219). Recombinant adenoviruses (Δ 7-43 apoA-I Ad5 and Δ 7-65 apoA-I Ad5) were prepared as previously described for the wild-type apoA-I (Wt apoA-I) adenovirus (Wt apoA-I Ad5) (219). Briefly, low passage human embryonic kidney (HEK) 293 cells were co-transfected at 40-60% confluency with 5 μ g of the pCA13 + apoA-I constructs and 6.5 μ g of pJM17, the plasmid containing the adenovirus genome. Homologous recombination upstream and downstream of the multiple cloning site generated a replication deficient (E1 deleted) adenovirus genome

Figure 3-1: Structural Elements of the Mutant ApoA-I s Expressed in ApoA-I Deficient Mice

Deletion of residues 7-43 removes the majority of the globular domain with the exception of residues 1-6, which are thought to adopt an unordered structure (272). The removal of residues 7-65 results in the deletion of the globular domain and of the 1st class A helix (a.a. 44-65).

containing the apoA-I cDNA. Following transfection, cells were overlaid with Eagles's minimal essential medium containing 0.65% SeaPlaque GTG agarose (FMC BioProducts) to isolate individual viral plaques. Post-transfection (6-14 days) viral plaques were isolated and screened by PCR amplification of the apoA-I cDNA. To do this, infected 293 cells were treated with 0.05% pronase (in 10 mM Tris-HCl, pH 7.5, 10 mM EDTA and 0.5% (w/v) SDS) at 37°C for 12 hours. Cell lysates were extracted once with phenol:chloroform:isoamylalcohol (25:24:1, v/v/v) and DNA precipitated from the aqueous phase using 96% ethanol. This was used as a template for PCR amplification of the apoA-I cDNA using upstream and downstream primers annealing to the CMV promoter and non-translated apoA-I sequence, respectively. Positive plaques were scaled-up and purified by CsCl gradient ultracentrifugation. Purified virus was titered by UV absorbance at 260 nm. Purified virus was diluted 1:1 with 0.1% SDS, 10 mM Tris-HCl (pH 7.4) and 1 mM EDTA and incubated at 56°C for 10 min and the concentration of viral particles determined according to the following equation:

$$\text{Concentration of Viral Stock (Viral Particles/mL)} = (\text{OD}_{260}) \times (\text{viral dilution}) \times 1.1 \times 10^{12}$$

Simultaneous plaque assays indicated approximately 18 viral particles per pfu, consistent with previous reports.

3.2.2 *Animals*

ApoA-I deficient (ApoA1^{tm1Unc}) mice were obtained from Jackson Laboratories. Mice were maintained on a 12 h light/12 h dark schedule and were fed a normal chow diet (Charles River rodent diet 5075 – 18% protein and 4.5% fat). All experiments were performed in accordance with protocols approved by the University of Ottawa Animal Care Committee. Mice used for these studies were all 4-12 month old males.

3.2.3 *Quantification of ApoA-I in Plasma*

Following adenovirus injections, plasma apoA-I levels were determined by quantitative Western blotting. Equivalent volumes of plasma were separated by 12% SDS-PAGE and analyzed by Western blot using a polyclonal anti-human apoA-I antibody raised in sheep. The concentrations of Wt apoA-I and the two N-terminal deletion mutants in mouse plasma samples were determined by densitometry and comparison to apoA-I standards of known concentrations using Quantity One software (BioRad). To eliminate the possibility that differential immunoreactivity may under or overestimate the plasma levels of the mutant apoA-I s expressed in the mouse, we compared the immunoreactivity of His-Wt apoA-I with the 2 N-terminal deletion mutants, His- Δ 1-43 and His- Δ 1-65 apoA-I. Equivalent amounts of the purified histidine-tagged apoA-I s (determined by Markwell and Lowry method (275)) were separated by SDS-PAGE and analyzed by Western blot. A mass range of 0.2-5 μ g was used, covering the range in apoA-I mass detected in plasma by this method. The relative intensity was then plotted versus the mass of apoA-I used for His-Wt, His- Δ 1-43 and His- Δ 1-65 apoA-I (data not shown). The plots were virtually identical indicating that differential immunoreactivity is not a concern in this assay.

3.2.4 *Size Exclusion Chromatography*

Separation of mouse plasma by size exclusion chromatography (FPLC) was performed as described previously (219). Briefly, 500 μ L of mouse plasma was passed through 2 Superdex 200 (analytical grade – Amersham Pharmacia Biotech) columns connected in series. Separation was achieved at a flow rate of 0.1 mL/min and 5 mL fractions were collected. Each fraction was assayed for TC Roche Diagnostics Corp.), FC

and PL content using standard enzymatic kits. Each fraction (100 μ L aliquot) was analyzed for apoA-I content by slot blot (BioRad Bio-Dot SF unit) followed by Western blot analysis using a biotinylated A44 monoclonal antibody.

3.2.5 *Discontinuous Gradient Ultracentrifugation*

ApoA-I deficient mouse plasma samples were separated by discontinuous gradient ultracentrifugation as described previously (219). Samples were centrifuged for 18 h and 210 000 \times g at 8°C. Fractions (1 mL) were collected from top to bottom and densities were determined by refractometer (Fisher Scientific) analysis. Aliquots of each fraction were dialyzed against PBS (0.025 μ m filter disks – Millipore Corp.) and analyzed by SDS-PAGE. Western blot analysis was performed using a polyclonal anti-human apoA-I antibody from sheep.

3.2.6 *Electron Microscopy*

Negative stain electron microscopy was performed as described by others (50). Briefly, discontinuous gradient samples were dialyzed against 0.125 M ammonium acetate, 2.6 mM ammonium carbonate and 0.26 mM EDTA, pH 7.4 and concentrated to 100-200 μ g/mL total protein. Samples were mixed 1:1 with sodium phosphotungstate, pH 7.4 before applying to carbon-coated Formvar grids (200 mesh) and visualized using a Hitachi H-7100 electron microscope at 50 000 and 70 000 \times magnification.

3.2.7 *Electrophoresis and Western Blotting*

Please refer to these protocols as outlined in the *Materials and Methods* section of Chapter 2.

3.3 Results

3.3.1 Generation of ApoA-I Recombinant Adenoviruses

The cDNAs for $\Delta 7-43$ and $\Delta 7-65$ apoA-I were constructed and subcloned into the pCA13 shuttle vector, as previously described for the cDNA encoding Wt apoA-I (219). Sequencing in both in the 5' \rightarrow 3' and 3' \rightarrow 5' orientations indicated that both deletions were correct and that no other mutations were present.

Following cotransfection of 293 cells, viral plaques were screened by PCR using primers that annealed in the CMV promoter and distal to the apoA-I stop codon, upstream and downstream of the apoA-I cDNA, respectively. The recombination step confers a reduction in Ad5 genome size, relative to pJM17, which is able to package into the viral capsid.

Potential viral plaques were screened by PCR amplification of the apoA-I cDNA. Electrophoretic separation of the amplified products in 1% agarose revealed the presence and expected size of Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I following ethidium bromide staining (Fig. 3-2). The plaques were scaled-up by repeated infections of 293 cells and purified by cesium chloride ultracentrifugation. The titers of the purified stocks of adenovirus were on the order of $0.5-2 \times 10^{11}$ p.f.u./mL.

3.3.2 ApoA-I and Lipid Levels Following Injection of Recombinant Adenoviruses

To explore the role of the N-terminus of apoA-I *in vivo*, we used recombinant adenovirus constructs to transiently express similar concentrations of Wt apoA-I and two N-terminal mutants ($\Delta 7-43$ and $\Delta 7-65$ apoA-I Ad5) in apoA-I deficient mice. Residues 1-6

Figure 3-2: PCR Amplification of ApoA-I cDNAs from 293 Cells Infected with Potential Wt, Δ 7-43 and Δ 7-65 ApoA-I Adenoviruses

HEK 293 cells infected with potential Wt, Δ 7-43 and Δ 7-65 apoA-I recombinant adenoviruses were lysed by treatment with 0.05% pronase. Cell lysates were treated with phenol:chloroform:isoamylalcohol and DNA in the aqueous phase subject to ethanol precipitation. PCR amplification of the apoA-I transgene indicated that cDNAs of the expected size for Wt (lanes 2 and 3), Δ 7-43 (lanes 4 and 5) and Δ 7-65 (lanes 6 and 7) were cloned into their respective recombinant adenoviruses.

were maintained to allow proper cleavage of the hexapeptide pro-sequence *in vivo* (see discussion). We have previously shown that apoA-I deficient mice express high levels of human apoA-I following tail vein administration of 2×10^9 p.f.u. of the recombinant adenovirus (219). To determine the expression levels of Δ 7-43 and Δ 7-65 apoA-I relative to Wt apoA-I, sex and age matched mice were injected with 2×10^9 p.f.u. of each respective adenovirus. Analysis of plasma lipid levels at various time points post-injection indicated that injection of this adenovirus dose was not associated with increases in plasma lipid levels above background for Δ 7-43 and Δ 7-65 apoA-I (Fig. 3-3). Analysis of fasting plasma samples 4 days post-injection indicated that Δ 7-43 (Fig.3-4, lane 4) and Δ 7-65 (Fig. 3-4, lane 6) apoA-I were expressed at approximately 4-fold lower levels than Wt apoA-I (Fig. 3-4, lane 3). In order to attain plasma levels of Δ 7-43 and Δ 7-65 apoA-I comparable to Wt apoA-I, a

4-fold greater dose (8×10^9 p.f.u.) of the $\Delta 7-43$ and $\Delta 7-65$ apoA-I Ad5 was used. We have shown previously that injection of up to 1×10^{10} p.f.u. of a luciferase Ad5 is not itself

Figure 3-3: Plasma Lipid Levels in ApoA-I Deficient Mice Post-Injection with Wt, $\Delta 7-43$ and $\Delta 7-65$ ApoA-I Adenoviruses

ApoA-I deficient mice were injected with 2×10^9 p.f.u. of Wt (●), $\Delta 7-43$ (▲) and $\Delta 7-65$ (■) apoA-I Ad5 and the plasma total cholesterol, FC, CE and PL levels determined using standard enzymatic kits.

associated with short- term changes in plasma lipid levels relative to non-injected mice (219). This is corroborated by others using similar adenovirus control vectors (286,287). Injecting 8×10^9 p.f.u. of the $\Delta 7-43$ (Fig. 3-4, lane 5) and $\Delta 7-65$ (Fig. 3-4, lane 7) apoA-I Ad5 resulted in plasma apoA-I levels comparable to Wt apoA-I and this dose was used for all subsequent experiments. Analysis of plasma lipid levels (Table 3-1) indicated that TC, FC and PL concentrations were increased significantly ($p < 0.05$, student's t-test) for Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I above those of non-injected controls. CE levels were increased ($p < 0.05$,

student's t-test) above background for Wt and $\Delta 7-43$ apoA-I but not for $\Delta 7-65$ apoA-I. The plasma CE/TC ratios in mice expressing $\Delta 7-43$ (0.49 ± 0.12) and $\Delta 7-65$ (0.25 ± 0.20) apoA-I

Figure 3-4: Relative Expression of Wt, $\Delta 7-43$ and $\Delta 7-65$ ApoA-I in ApoA-I Deficient Mouse Plasma Following Adenovirus Injection.

ApoA-I deficient mice were injected with 2×10^9 pfu of Wt apoA-I Ad5 (lane 3), 2×10^9 and 8×10^9 pfu of $\Delta 7-43$ apoA-I Ad5 (lanes 4 and 5, respectively) and 2×10^9 and 8×10^9 pfu of $\Delta 7-65$ apoA-I Ad5 (lanes 6 and 7, respectively). Equal volumes of plasma were separated by 12% SDS-PAGE and visualized by Coomassie blue staining (A) and anti-human apoA-I Western blotting using a polyclonal antibody from sheep (B). A human apoA-I standard and non-injected apoA-I deficient mouse plasma are shown in lanes 1 and 2, respectively.

significantly reduced relative to those expressing Wt apoA-I.

3.3.3 FPLC Analysis of Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I containing HDL

Fasting plasma samples from apoA-I deficient mice 4 days post-injection with 2×10^9 p.f.u. of Wt apoA-I Ad5 or 8×10^9 p.f.u. of $\Delta 7-43$ and $\Delta 7-65$ apoA-I Ad5 were separated by size exclusion chromatography. Individual fractions were assayed for TC content (Fig. 3-5A) and relative apoA-I distribution by slot blot analysis (Fig. 3-5B). This indicates that Wt, $\Delta 7-$

43 and Δ 7-65 apoA-I associate with lipoproteins of HDL size. In each case, the plasma lipoprotein size distribution is shifted to a similar extent for each of these apoA-I proteins

Table 3-1: ApoA-I, cholesterol (total, free and esterified) and phospholipid levels were determined 4 days post-injection with apoA-I recombinant adenoviruses.

	ApoA-I	TC	FC	CE	PL	CE/TC
	<i>mg/dL</i>					
None (n=3)	-	42 ± 6 ^b	25 ± 5 ^b	16 ± 3 ^b	106 ± 40 ^b	0.39 ± 0.07 ^b
Wt ApoA-I [†] (n=5)	294 ± 40	125 ± 24 ^a	44 ± 9 ^a	81 ± 22 ^a	226 ± 38 ^a	0.64 ± 0.07 ^a
Δ 7-43 ApoA-I [‡] (n=5)	287 ± 63	102 ± 25 ^a	53 ± 19 ^a	50 ± 16 ^{a,b}	201 ± 49 ^a	0.49 ± 0.12 ^b
Δ 7-65 ApoA-I [‡] (n=3)	278 ± 41	83 ± 4 ^{a,b}	62 ± 13 ^a	21 ± 17 ^b	211 ± 18 ^a	0.25 ± 0.20 ^b

2×10^9 pfu ([†]) or 8×10^9 pfu ([‡]) of recombinant adenovirus was injected and the mouse plasma sampled 4 days post-injection following a 10 h fast. All mice were male apoA-I deficient mice 6-10 months of age. ApoA-I, TC, FC and PL levels were determined as described in *Materials & Methods*. Plasma CE concentrations were taken as the difference between TC and FC levels. Values represent the mean ± SE.

^aValues significantly different ($p < 0.05$, student's t-test) than non-injected mice.

^bValues significantly different ($p < 0.05$, student's t-test) than Wt apoA-I Ad5 injected mice.

relative to that of the non-injected apoA-I deficient mouse (Fig. 3-5A). The shift in HDL size relative to the non-injected mouse was due to the replacement of apoE with apoA-I on these HDL. We have shown previously that *de novo* expression of Wt apoA-I reduces plasma concentrations of apoE in the apoA-I deficient mouse following adenovirus administration (219) and appears to occur to similar extents for Wt, Δ 7-43 and Δ 7-65 apoA-I (Fig. 3-5A, inset). Despite lower plasma cholesterol levels associated with Δ 7-43 and Δ 7-65 apoA-I,

HDL and apoA-I distributions were not significantly altered as compared to Wt apoA-I. In addition, Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I did not associate with a lipid-free/poor pool (fractions 26-28) as all detectable apoA-I co-localized with the HDL cholesterol peak.

Figure 3-5: Analysis of Wt, $\Delta 7-43$ and $\Delta 7-65$ ApoA-I Containing HDL by Size Exclusion Chromatography.

ApoA-I deficient mouse plasma 4 days post-injection with 2×10^9 pfu of Wt apoA-I Ad5 (● and 1), 8×10^9 pfu of $\Delta 7-43$ apoA-I Ad5 (▲ and 2) and 8×10^9 pfu of $\Delta 7-65$ apoA-I Ad5 (■ and 3) was separated by size exclusion chromatography (see *Materials and Methods*). Individual fractions were sampled for TC content (A) and apoA-I distribution by slot blot analysis followed by anti-human apoA-I Western blotting using the A44 monoclonal antibody (B). In addition, the FPLC cholesterol profile of non-injected apoA-I deficient mouse plasma is shown (♦). The inset shows a Western blot of mouse plasma apoE before (lane 2a) and 4 days post-injection with Wt (lane 3a), $\Delta 7-43$ (lane 4a) and $\Delta 7-65$ (lane 5a) apoA-I Ad5. Relative expression of apoE in wild-type C57BL/6J mice not injected with adenovirus is shown for reference (lane 1a).

Subsequently, the TC, FC, CE and PL content in FPLC fractions corresponding to HDL size were normalized to the respective apoA-I concentrations. As compared to Wt apoA-I

HDL, $\Delta 7-43$ and, more markedly, $\Delta 7-65$ apoA-I HDL contained less TC, on average, per HDL particle (Fig. 3-6A). This is predominantly due to a reduced CE content for $\Delta 7-43$

Figure 3-6: Relative Lipid Composition of Wt, $\Delta 7-43$ and $\Delta 7-65$ ApoA-I HDL

TC (A), FC (B), CE (C) and PL (D) levels in FPLC fractions corresponding to HDL size were normalized to the respective apoA-I protein mass. The resultant profiles represent the relative lipid content of HDL containing Wt (●), $\Delta 7-43$ (▲) and $\Delta 7-65$ (■) apoA-I. The lipid measurements were done using enzymatic kits (see *Materials and Methods*).

and, more markedly, $\Delta 7-65$ apoA-I HDL as compared to Wt apoA-I HDL (Fig. 3-6C).

Furthermore, Wt apoA-I HDL contained more PL than $\Delta 7-43$ or $\Delta 7-65$ apoA-I HDL (Fig.

3-6D), however, this reduction was proportionately less than that observed for CE.

3.3.4 Agarose and PAGGE Separation of Wt, $\Delta 7-43$ and $\Delta 7-65$ ApoA-I HDL

Mouse plasma samples were isolated 4 days following injection of either the Wt, $\Delta 7-43$ or $\Delta 7-65$ apoA-I Ad5. The relative amounts of pre β - and α -HDL associated with each of the apoA-I proteins were evaluated by agarose gel electrophoresis. HDL were visualized either by neutral lipid staining (Fig. 3-7A) or Western blot analysis with an anti-human apoA-I monoclonal antibody (Fig. 3-7B). Two independent apoA-I Ad5 injections are shown in each panel and are representative of 4 separate injections. Expression of Wt apoA-I was associated with high levels of α -migrating neutral lipid staining (Fig. 3-7A, lanes 3, 4) and was consistent with the position of Wt apoA-I by Western blot (Fig. 3-7B, lanes 3, 4). $\Delta 7-43$ apoA-I associated HDL migrated predominantly to the α -position (Fig. 3-7B, lanes 5, 6) and accumulated significant levels of neutral lipid (Fig. 3-7A, lanes 5, 6), although less than observed for Wt apoA-I. In addition, $\Delta 7-43$ apoA-I formed more pre β -HDL than was observed for Wt apoA-I. Strikingly, $\Delta 7-65$ apoA-I formed only pre β -HDL as demonstrated by Western blot analysis (Fig. 3-7B, lanes 7, 8) and neutral lipid staining (Fig. 3-7A, lanes 7, 8) (no α -migrating HDL detected).

Non-denaturing PAGGE was next used to determine the size of HDL formed with Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I. Wt (Fig. 3-7C, lanes 3, 4) and $\Delta 7-43$ (Fig. 3-7C, lanes 5, 6) apoA-I formed 2 distinct HDL pools (10.1 – 10.7 nm and 8.8 – 9.9 nm) similar in size to each other and to a human HDL standard (10.3 – 11.0 nm and 8.8 – 9.9 nm) (Fig. 3-7C, lanes 1). In contrast, $\Delta 7-65$ (Fig. 3-7C, lanes 7, 8) apoA-I formed a more heterogeneous HDL population. The predominant species was of similar size to Wt and $\Delta 7-43$ apoA-I HDL (10.3 nm) but included additional species of 11.6 nm, 11.1 nm, 9.4 nm and 8.8 nm in diameter.

Figure 3-7: Characterization of Wt, $\Delta 7-43$ and $\Delta 7-65$ ApoA-I HDL by Agarose and Non-Denaturing PAGE

(A, B) Mouse plasma 4 days post-injection with Wt (lanes 3, 4), $\Delta 7-43$ (lanes 5, 6) and $\Delta 7-65$ (lanes 7, 8) apoA-I Ad5 were separated by agarose electrophoresis and visualized by neutral lipid staining (A) and anti-apoA-I Western blotting (B) using the biot-A44 mAb. Human HDL (lane 1), non-injected apoA-I deficient mouse plasma (lane 2), human LDL (lane 9) and wild-type apoA-I (lane 10) are shown for reference.

3.3.5 Effect of Apo-I N-Terminal Deletions on HDL Morphology

ApoA-I deficient mouse plasma 4 days post-injection with 2×10^9 p.f.u. of Wt apoA-I Ad5 and 8×10^9 p.f.u. of $\Delta 7-43$ and $\Delta 7-65$ apoA-I Ad5 was separated by discontinuous density gradient ultracentrifugation (Fig. 3-8). The density distributions of Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I HDL were very similar with $\Delta 7-65$ apoA-I HDL shifted to a peak density of 1.12 g/mL relative to Wt and $\Delta 7-43$ apoA-I HDL at 1.06-1.09 g/mL. The morphology of these HDL particles was determined by negative stain electron microscopy. Wt apoA-I HDL (Fig. 3-9B) exhibited a typical hexagonal packing array characteristic of spherical HDL.

Figure 3-8: Density Separation of ApoA-I Deficient Mouse Plasma 4 Days Post-Injection with Wt, $\Delta 7-43$ and $\Delta 7-65$ ApoA-I Ad5.

ApoA-I deficient mice were injected with either 2×10^9 p.f.u. of Wt (A) apoA-I Ad5 or 8×10^9 p.f.u. of $\Delta 7-43$ (B) and $\Delta 7-65$ (C) apoA-I Ad5 and the plasma collected 4 days post-injection in the fasted state. Plasma samples were separated by gradient ultracentrifugation and individual gradient samples were further subject to 12% SDS-PAGE. A Western blot using a sheep polyclonal anti-human apoA-I antibody of the electrophoretic separation is shown.

HDL associated with $\Delta 7-43$ (Fig. 3-9C, D) apoA-I were predominantly spherical and comparable in size to Wt apoA-I HDL, although some discoidal HDL were present. In contrast, expression of $\Delta 7-65$ (Fig. 3-9E, F) apoA-I was consistently associated with abnormal HDL morphology. These lipoproteins presented as 'rouleaux' of stacked structures characteristic of discoidal HDL. These discoidal particles were absent in non-injected (not shown) and luc-Ad5 apoA-I deficient mice (Fig. 3-9A), which demonstrates that these HDL formed as a consequence of expressing this mutant apoA-I.

Figure 3-9: Effect of ApoA-I N-terminal Deletions on HDL Morphology

ApoA-I deficient mouse plasma HDL formed 4 days post-injection with luc- (panel A, $\rho=1.09\text{g/mL}$), Wt (panel B, $\rho=1.06\text{ g/mL}$), $\Delta 7\text{-}43$ (panel C, $\rho=1.06\text{ g/mL}$) (panel D, $\rho=1.09\text{ g/mL}$) and $\Delta 7\text{-}65$ (panel E and F, $\rho=1.12\text{g/mL}$) apoA-I Ad5 were isolated by discontinuous gradient ultracentrifugation and visualized by negative stain electron microscopy as described in *Materials and Methods*. The bar in each panel represents 100 nm. Electron micrographs were taken at 50 000X magnification in panels A and E whereas panels B, C, D and F were taken at 70 000X magnification.

3.4 Discussion

The use of animal models to corroborate apoA-I structure-function relationships observed *in vitro* has been described previously. To further address the contribution of the globular domain and helix 1 of apoA-I in HDL metabolism, we expressed Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I in apoA-I deficient mice by adenovirus-mediated gene transfer. ApoA-I is secreted as a proprotein containing 6 additional residues at the N-terminus that are removed by a putative metalloprotease which recognizes residues -2 to +4 and cleaves the pro-sequence thereby generating the mature protein (167). Therefore, residues 1-6 were not removed when constructing the cDNAs for *in vivo* expression to enable proper processing of these mutants. Plasma concentrations of $\Delta 7-43$ and $\Delta 7-65$ apoA-I were decreased 4-fold relative to Wt apoA-I when compared 4 days post-injection with 2×10^9 p.f.u. of recombinant adenovirus (Fig. 3-4). We have previously shown that deletions of residues 100-143, 122-165, 144-186 (219) and 210-243 (unpublished observations) also result in significantly lower levels of these apoA-I mutants in plasma following adenovirus-mediated expression. In the current study, this was not due to impaired secretion as pulse-chase analysis indicated that both mutants were secreted as efficiently as Wt apoA-I from primary apoA-I deficient hepatocytes (data not shown). The lower expression of $\Delta 7-43$ and $\Delta 7-65$ apoA-I may result from decreased stability of these proteins in the lipid-free form as similar deletions have been shown to significantly alter the conformation of apoA-I in solution (199). Alternatively, reduced PL binding affinity may account for this observation as this property associates with a greater fractional catabolic rate amongst some apoA-I mutants (214). Injection of a 4-fold greater dose of the $\Delta 7-43$ and $\Delta 7-65$ apoA-I Ad5 resulted in plasma levels of these proteins similar to Wt apoA-I (Fig. 3-4, Table 3-1). Analysis of plasma lipid

concentrations indicated that the CE/TC ratio for both the $\Delta 7-43$ and, more markedly, $\Delta 7-65$ apoA-I Ad5 injected mice was significantly reduced relative to Wt apoA-I Ad5. This observation corroborates our *in vitro* observations as the deletion of these residues decreases LCAT activation. The size distribution of the lipoproteins formed by these mutants was analyzed by size exclusion chromatography (Fig. 3-5) and demonstrated that Wt, $\Delta 7-43$ and $\Delta 7-65$ apoA-I were associated exclusively with lipoproteins of HDL size. This indicates the plasma CE/TC ratios discussed previously are representative of HDL composition.

Analysis of HDL by agarose gel electrophoresis (Fig. 3-7A, B) indicated both $\Delta 7-43$ and $\Delta 7-65$ apoA-I formed progressively more pre β -HDL as compared to Wt apoA-I. However, unexpectedly based on our *in vitro* observations addressed in Chapter 2, $\Delta 7-65$ apoA-I was unable to form α -migrating HDL. Davidson and coworkers characterized the molecular basis governing the surface charge of pre β - and α -migrating HDL (29). They found the greatest contributors were phosphatidylinositol content and the presence of a neutral lipid ester core. While the lipid core does not directly contribute to the lipoprotein charge, conformational changes in the surface apolipoproteins are believed to confer this effect. The increases in pre β -HDL and reductions in α -migrating HDL associated with $\Delta 7-43$ and $\Delta 7-65$ apoA-I HDL might be linked to a gradual impairment in LCAT activation with progressive deletion of the N-terminus. This postulate is supported by the progressive loss of HDL-CE content associated with these apoA-I deletions.

Analysis of HDL size by non-denaturing PAGE indicated that $\Delta 7-65$ apoA-I HDL were significantly more heterogeneous in size than either Wt or $\Delta 7-43$ apoA-I HDL (Fig. 3-7C). In human plasma, pre β -HDL constitutes 4–14% of total HDL and consists of pre β_1 , pre β_2 and pre β_3 subtypes (reviewed in ref (15)). Pre β_1 -HDL are on average 5.6 nm in

diameter and are considered the initial acceptors of cellular FC. Pre β_2 and pre β_3 -HDL have greater FC and PL contents and are significantly larger, in the range of 10-14 nm in diameter. Furthermore, pre β -HDL contains little, if any, CE, which associates with α -migrating HDL_{2/3}. $\Delta 7-65$ apoA-I HDL corresponded to pre β_2 /pre β_3 in size and suggests that HDL maturation may be impaired at the level of conversion of these subtypes to α -migrating HDL.

Electron microscopic analysis of HDL formed by these mutants (Fig. 3-9) indicated $\Delta 7-65$ apoA-I formed exclusively stacked 'rouleaux' of discoidal HDL while $\Delta 7-43$ and Wt apoA-I formed predominantly spherical HDL with typical hexagonal packing arrays. The appearance of discoidal HDL associated with $\Delta 7-65$ apoA-I was anticipated based upon a drastically reduced CE/TC ratio in the plasma and predominant pre β - migration on agarose gels.

In summary, this work demonstrates that the N-terminus of apoA-I is important for the *in vivo* maturation of HDL. Deletion of the globular domain alone reduces plasma apoA-I levels and reduces the CE content of HDL. The additional deletion of residues 44-65 further reduces the CE content of HDL and impairs the ability of apoA-I to form spherical HDL.

CHAPTER 4: CONCLUSIONS

The use of naturally-occurring and engineered mutations, synthetic peptides, monoclonal antibodies, proteolytic digestion and chemical modification have been employed to delineate apoA-I structure-function relationships. However, to date most studies have addressed the role(s) of helices in the central (residues 100-186) and C-terminal (residues 187-243) domains while the involvement of the N-terminus remains poorly understood.

The globular domain (residues 1-43) is encoded in exon 3 while the remainder of apoA-I is derived from exon 4, providing rationale at the genomic level for considering this region independently from the rest of the protein structure. This region contains an amphipathic α -helix (residues 8-33) of the G* class and differs from the helices in the rest of apoA-I, which are of class A and Y (188). While G* helices have reduced lipid-binding affinity relative to class A or Y, analysis of a synthetic peptide analogous to residues 1-33 of apoA-I indicates these residues have moderate affinity for phospholipid relative to other apoA-I peptides (221). G* helices are present within 5 of the 7 exchangeable apolipoproteins: apoA-I, apoA-IV, apoC-II, apoC-III and apoE. A Δ 1-43 apoA-I has been described previously (189,197,199,220). These studies suggest that the globular domain is involved in the maintenance of the lipid-free conformation of apoA-I, which has been proposed to constitute a helical bundle encompassing residues 1-187 in tryptophan fluorescence (288) and limited proteolysis (195) experiments. Proposing this mutant may adopt a conformation in solution analogous to the lipid-bound form, it was subsequently crystallized by Borhani *et al.* to determine the lipid-bound topology of apoA-I (189). The X-ray crystal structure suggests that apoA-I wraps around the periphery of the HDL particle perpendicular to the phospholipid fatty-acyl chains, an orientation referred to as the 'belt' model. However, deletion of these residues also confers a 2-fold reduction in the ability of

apoA-I to activate LCAT suggesting functional properties of this mutant may be affected as well.

The importance of helix 1 (residues 44-65) for PL association has been shown previously (212,220). Using synthetic peptides modeled after repeating 22-mer domains of apoA-I, Palgunachari *et al.* demonstrated that only N- and C- terminal peptides corresponding to residues 44-65 and 220-241 were able to clarify DMPC liposomes implicating both the N- and C-terminus in PL binding (212). Characterization of a Δ 1-65 apoA-I deletion mutant using POPC vesicular binding assay suggested this protein had significantly less lipid affinity relative to Wt and Δ 1-43 apoA-I. However, the contribution of this helix to cholesterol efflux, LCAT activation and the *in vivo* maturation of HDL has not been determined.

Several naturally-occurring mutations in the N-terminus of apoA-I have been described (reviewed in refs (78)), however, their effects on HDL metabolism have not been well characterized. ApoA-I Iowa (Gly²⁶→Arg) is associated with hereditary systemic amyloidosis (289), low plasma levels of HDL and apoA-I and has been shown to have enhanced catabolism when infused into normal subjects (290). This mutation lies within the G* helix in the globular domain, suggesting that disruption of this helix alters structural and/or functional properties of apoA-I. Point-mutations in helix 1 have also been identified (291-293). Unfortunately, it appears that the effects of these mutations on apoA-I and HDL levels have not been fully reported. As amyloidogenic mutations are proposed to perturb structural properties of apoA-I, a detailed analysis of these mutants may clarify the role(s) of these helical domains in HDL metabolism. Furthermore, Booth and coworkers reported a novel apoA-I deletion/insertion where residues 60 to 71 were deleted and replaced by single

valine and threonine residues, disrupting a portion of helix 1 (294). This mutant was associated with significantly lower apoA-I and HDL levels.

Therefore, limited analysis of naturally occurring mutations in the N-terminus of apoA-I suggests more detailed studies are warranted to delineate functional properties associated with this region. We have evaluated the contribution of the globular domain (a.a. 1-43) and the first class A amphipathic α -helix (a.a. 44-65) in HDL maturation both *in vitro* and *in vivo*.

In Chapter 2 we demonstrated that deletion of the amino-terminus greatly reduced the ability of apoA-I to bind PL and to activate LCAT without affecting cholesterol efflux. The contribution of the globular domain and helix 1 to the native-lipid binding properties of apoA-I is consistent with previous studies using synthetic apoA-I peptides. In particular, the involvement of residues 44-65 in the initial phases of PL binding is well established, in which the two end helices of apoA-I are thought to mediate this interaction. Gillotte *et al.* have also suggested that the association of apoA-I with cell membranes may also be mediated by these helices and may facilitate the acquisition of membrane PL and cholesterol (249). This hypothesis is not supported by our work, which indicates that cell association and cholesterol efflux is not dependent upon the presence of residues 44-65. A potential importance of the G* domain in PL binding is not well established but is suggested by this work. The reduced rate of DMPC clearance may be due to the affect of this deletion on apoA-I conformation and an effect of PL binding may be secondary. Okon *et al.* have suggested the G* helix, because of its moderate lipid affinity and the fact that it is separated from the rest of the protein by 11 residues of unordered structure, may be capable of dissociating from the HDL surface for interaction with cell surface receptors, lipid transfer protein or lipolytic enzymes (272). This hypothesis has yet to be corroborated by any

functional data. Clearly the deletion of the extreme N-terminus of apoA-I reduced the capacity of apoA-I to activate LCAT. This effect was conferred by both the deletion of residues 1-43 and the subsequent removal of residues 44-65. Rogers *et al.* have also demonstrated that the globular domain of apoA-I is involved in LCAT activation and observed a similar reduction of approximately 2-fold in the V_{\max} (197). The observation that deletion of helix 1 affects LCAT activation is novel as previous work by Rogers *et al.* was unable to differentiate between lipid-binding affinity and LCAT activation (197). Our work suggests that the extreme amino-terminus of apoA-I differs significantly from both the central (a.a. 100-186) and C-terminal (a.a. 187-243) domains because only the deletion of the N-terminus affects both phospholipid binding and LCAT activation.

In order to evaluate the importance of the amino-terminus of apoA-I for the *in vivo* maturation of HDL, we generated recombinant adenovirus vectors for the transient expression of Wt, Δ 7-43 and Δ 7-65 apoA-I in apoA-I deficient mice. We observed that these deletions did not affect the secretion rate of apoA-I from primary apoA-I deficient hepatocytes (data not shown) but did result in a 4-fold reduction in plasma apoA-I levels 4 days post-injection relative to Wt apoA-I. Injection of a 4-fold greater adenovirus dose for the 2 mutants resulted in similar plasma levels of apoA-I, however, the plasma CE/TC ratio was greatly reduced for Δ 7-43 and, more markedly, Δ 7-65 apoA-I injected mice. Δ 7-65 apoA-I associated HDL were found to be predominantly pre β - migrating while Δ 7-43 and Wt apoA-I HDL were mostly α - migrating. This was corroborated by electron microscopic examination, which revealed that Δ 7-65 apoA-I HDL were of discoidal morphology whereas Δ 7-43 and Wt apoA-I HDL were spherical. As opposed to the *in vitro* studies of Chapter 2, the *in vivo* model suggests that the further deletion of residues 44-65 significantly disrupted

physical and/or functional properties of apoA-I resulting in the inability to form mature α -HDL.

The *in vitro* studies suggest that the reduced CE content of HDL containing Δ 7-43 or Δ 7-65 apoA-I HDL observed *in vivo* can be attributed to a reduced capacity of these mutants to activate LCAT. Furthermore, the effect conferred by the deletion of residues 7-65 on HDL morphology seems far greater than might be predicted based solely on a reduced capacity to activate LCAT. It is conceivable that the first class A helix, based on its high lipid-binding affinity, may also indirectly contribute to the CE enrichment of HDL, such as stabilizing apoA-I during the conversion of pre β _{2,3}-HDL to spherical, α -migrating HDL.

In summary, we have shown that the globular domain (a.a. 1-43) and helix 1 (a.a. 44-65) of apoA-I are important for HDL maturation *in vivo*. Removal of the globular domain alone decreases plasma apoA-I levels and significantly reduces the cholesterol content of HDL (and lowers the CE/TC ratio). This supports current and previous *in vitro* findings that the globular domain is involved in LCAT activation and suggests this domain contributes to steady-state concentrations of HDL. The subsequent deletion of residues 44-65 further reduces the ability of apoA-I to activate LCAT *in vitro*. A reduced capacity to activate LCAT directly may account for the inability of Δ 7-65 apoA-I to form spherical α -migrating HDL. Alternatively, in addition to a direct effect of this deletion on LCAT activation, helix 1 may contribute to the accumulation or stabilization of core neutral lipids and transformation of pre β - into α -migrating HDL. This latter effect could involve the high affinity of this specific helix for PL. This is the first demonstration that the globular domain and helix 1 of apoA-I are essential for the formation of mature HDL in a physiologically relevant animal model.

CURRICULUM VITAE

BRIAN R. SCOTT

SUMMARY

Master's degree in biochemistry with extensive experience in protein expression, purification and characterization. Experience generating and utilizing adenovirus gene therapy vectors. Strong background in enzyme kinetics. Excellent training in the use of various chromatographic methods of protein separation. Extensive prior use of molecular biology techniques including PCR, mutagenesis and cloning. Excellent oral presentation skills and a solid publication history. Self-motivated, resourceful and creative individual with strong analytical, problem solving, decision making and interpersonal skills. Bilingual – French and English.

POST-SECONDARY EDUCATION

Jan. 2002 **MASTER'S DEGREE CANDIDATE – BIOCHEMISTRY**
University of Ottawa

May 1999 **BACHELOR'S DEGREE – BIOCHEMISTRY**
University of Ottawa

Areas of Study:

- Lipoprotein Metabolism
- Genetics
- Pharmacology
- Computer Applications
- Business
- Molecular Biology
- Organic Chemistry
- Toxicology
- Spectroscopy
- Statistics

WORK EXPERIENCE

Jan. 2000- **TEACHING ASSISTANT**
May 2000 University of Ottawa

May 1997- **UNDERGRADUATE RESEARCH STUDENT**
May 1999 Ottawa Heart Institute

Jan. 1997- **LABORATORY TECHNICIAN**
May 1997 Ottawa Hospital – Department of Pathology and Laboratory Medicine

SKILLS AND KNOWLEDGE ACQUIRED THROUGH TRAINING AND EXPERIENCE

- Extensive experience in protein expression and purification in *E. coli* and in cultured eukaryotic cells
- Chromatographic methods of protein separation including ion-exchange, affinity, gel filtration and high pressure liquid chromatography (HPLC)
- Performed enzyme kinetic analysis and used statistical and graphing software to interpret results
- Use of monoclonal/polyclonal antibodies including the development of large scale radioimmunoassays and ELISA
- Development of ligand binding assays both *in vitro* and in cell culture
- Employed many genetic and molecular biology techniques including DNA sequencing, cloning, use of restriction enzymes and polymerase chain reaction (PCR)
- Experience in virology and the use of adenovirus gene therapy vectors
- Prior training in the Workplace Hazardous Materials Information System (WHMIS)
- Experience in training and teaching other laboratory staff
- Excellent oral presentation and scientific writing skills
- Solid communication skills in both French and English

ACADEMIC ACHIEVEMENTS

Master's Thesis

Structure-Function Relationships of Human Apolipoprotein A-I: Role of the Amino-Terminal Amphipathic Alpha-Helices

Our research, conducted at the Ottawa Heart Institute, focused on apolipoprotein A-I (apoA-I), the predominant protein constituent of high density lipoproteins (HDL), and the mechanisms by which this protein protects against the development of atherosclerosis. To this end, wild-type apoA-I and various deletion mutants thereof were expressed and purified from *E. coli* and characterized using a multitude of structural biochemical studies and enzymatic analysis. In addition, using an *in vivo* approach, similar proteins were transiently expressed in apoA-I deficient mice using recombinant adenovirus vectors. The HDL formed containing the wild-type and mutant forms of apoA-I were isolated and used for biochemical analysis. This work was presented at 2 research conferences and was recently published in the Journal of Biological Chemistry.

Research Scholarships

Natural Sciences and Engineering Research Council (NSERC) of Canada Post-Graduate Scholarship

Ontario Post-Graduate Research Scholarship

NSERC Undergraduate Research Scholarship

Bill Schultz Undergraduate Research Scholarship – Heart & Stroke Foundation of Ontario

Recent Presentations

- Apr. 2001 **LIPOPROTEIN AND ATHEROSCLEROSIS GROUP SEMINAR**
A detailed review and analysis of my research was presented to the Lipoprotein research group at the Ottawa Heart Institute.
- Apr. 2001 **2001 OTTAWA HEART INSTITUTE RESEARCH COMPETITION**
Presentation entitled 'The Contribution of the Amino-Terminus of Apolipoprotein A-I to Reverse Cholesterol Transport' was presented as part of the students' competition during this annual research event.
- Mar. 2001 **DEPARTMENTAL SEMINAR**
Oral research presentation given to the professors and students of the Department of Biochemistry, Microbiology and Immunology at the University of Ottawa.
- Oct. 2000 **2000 CANADIAN LIPOPROTEIN RESEARCH CONFERENCE**
A poster presentation entitled 'The In Vivo Characterization of the Amino-Terminus of Apolipoprotein A-I' was delivered at this annual research conference.

COMPUTER SKILLS

- Working knowledge of Windows operating systems
- Proficient in Microsoft Word, Excel and Powerpoint
- Experience using scientific graphing software (ex. Sigmaplot)

PERSONAL ATTRIBUTES

- Works well under pressure within a fast-paced environment
- Able to coordinate and prioritize workload to meet stringent deadlines
- Fast learner; can grasp and apply new procedures/techniques quickly
- Interact cooperatively within a team environment
- Adapt readily to the demands of the position, including new challenges and work environments

HOBBIES AND INTERESTS

- Coaching high school volleyball
- Tutoring
- Golf, kayaking, squash and running
- Hiking and camping

CONTRIBUTIONS OF COLLABORATORS

Dan C. McManus

Dr. McManus generated the Wt and $\Delta 7-65$ apoA-I Ad5 constructs used for the *in vivo* characterization of the amino-terminus of apoA-I.

Vivian Franklin

Ms. Franklin expressed and purified the His-Wt apoA-I protein and performed the purification steps for all other His-apoA-I deletion mutants.

Andrea G. McKenzie

Miss McKenzie helped to generate the His- $\Delta 210-243$ apoA-I construct and optimize the conditions of its expression.

Phillippe Frank

During the course of his Ph.D studentship, Dr. Frank established the conditions for the purification of histidine-tagged apoA-I in our laboratory.

Christie G. Brouillette and Jeffrey A. Engler

The histidine-tagged $\Delta 1-65$ apoA-I cDNA cloned into the pGEMX prokaryotic expression vector was generously donated by Drs. Brouillette and Engler for this work.

Peter Rippstein

Mr. Rippstein was involved in the electron microscopic examination of the HDL samples isolated from apoA-I deficient mice. He performed the carbon coating of the formvar grids and provided some general tutelage as to the use of the microscope.
