## Abstract

Defective chromatin remodeling proteins are associated with both germline and acquired human disease. PHF6 is encoded by an X-linked gene that is predominantly expressed in the brain and thymus. Structurally, PHF6 contains nuclear and nucleolar localization sequences as well as two ZaP domains, which bind dsDNA. Germline mutations in PHF6 are the cause of BFLS, an XLID, while somatic PHF6 mutations have been identified in T-ALL, AML, and CML. Indeed, screening of a pediatric cohort of nine T-ALL patients revealed a novel H329Q mutation. In a further clinical analysis, T-ALL onset occurred in a 9-year old male BFLS patient with an R342X mutation, suggesting that BFLS might be a cancer predisposition syndrome. To better understand its protein function, recombinant PHF6 was co-immunoprecipitated for a mass spectrometry based proteomic screen. Notably, PHF6 co-purified with multiple constituents of the NuRD complex, an important transcriptional regulator during embryogenesis and lineage commitment with particularly well characterized responsibilities during lymphogenesis. PHF6-NuRD localization was restricted to the nucleoplasm, however PHF6 also co-purified with several ribosomal and splicing proteins. When examined further, PHF6 was found to be recruited to the nucleolus by an RNA-mediated interaction and co-localized within the subnucleolar FC and DFC compartments. CHIP-qPCR revealed that PHF6 binds to transcribed regions of rDNA, resulting in the repression of rRNA. These data thus present a model of PHF6 acting as a tumour suppressor by mediating both nucleoplasmic and nucleolar transcriptional events.

## Acknowledgements

I would like to foremost thank my supervisor Dr. David Picketts for the mentorship, training, and opportunities from which I have benefitted during my graduate studies. David has guided me with both the personal and professional values that I will always strive to emulate in my future career. I would also like to acknowledge the critical support and feedback provided by the members of my thesis advisory committee: Dr. Rashmi Kothary, Dr. Robin Parks, and Dr. Laura Trinkle-Mulcahy; as well as staff at the Ottawa Hospital Research Institute and the University of Ottawa for the necessary resources and facilities to support my graduate research and degree requirements.

Throughout my time in the Picketts lab, I have formed important friendships and collaborations that will persist beyond my training. While too numerous to recount in their entirety, I offer my particular thanks to Dr. Michael Huh, Dr. Darren Yip, Lemuel Racacho, Dr. Dennis Bulman, as well as all members of the Picketts lab, past and present, that I have had the pleasure of working alongside: Dr. Pamela Lagali, Keqin Yan, Danton Ivanochko, Dr. Matias Alvarez-Saavedra, Emile Hashem, Maureen Curtin, Steve Rennick, Chelsea McGregor, Marilyne Delorme, Emma Goodall, Tina Price O'Dea, Chantal Medina, Yusuf Ahmad, Olivia Zhang, Mélissa Geoffroy, and Khalid Al-Zahrani.

Finally, I thank all of my family and friends. You are the support system that instills within me the resolve and passion to pursue a career where I endeavour to answer the basic questions of life itself, and I am immensely grateful.

# Contents

<b>Chapter 1. General Introduction</b> .....	<b>1</b>
1.1 Chromatin remodeling mechanisms .....	2
1.1.1 DNA methylation .....	2
1.1.2 Covalent histone modifications .....	4
1.1.3 Chromatin remodeling complexes in human disease .....	9
1.2 The molecular genetics of <i>PHF6</i> .....	12
1.2.1 PHF6 structural features and functional studies in animal models ...	12
1.2.2 PHF6 mutations in Börjeson-Forssman-Lehmann syndrome .....	16
1.2.3 PHF6 mutations in T-cell acute lymphoblastic leukemia .....	19
1.2.3 PHF6 mutations in acute myeloid leukemia .....	22
1.2.4 Understanding how PHF6 mutations contribute to BFLS, T-ALL, And AML .....	23
1.3 Epigenetic regulation of rRNA synthesis in the nucleolus .....	24
1.3.1 Background .....	24
1.3.2 The epigenetics of rDNA transcription .....	27
1.3.3 Nucleolar regulation by the cell cycle and environmental stress ...	31
1.3.4 PHF6 in the nucleolus .....	33
1.4 Rationale, Hypothesis, and Specific Aims .....	34
1.4.1 To understand how PHF6 mutations may predispose BFLS patients to T-ALL .....	34
1.4.2 To identify and characterize PHF6 protein interactions .....	34
1.4.3 To identify a nucleolar function for PHF6 .....	35

# **CHAPTER 1**

## **General Introduction**

## 1.1 CHROMATIN REMODELING MECHANISMS

Epigenetic mechanisms are responsible for regulating the structural composition of DNA to influence the means by which genetic information is, or is not, replicated or expressed in the form of RNA and protein. In eukaryotes, epigenetic factors are required to accommodate the compaction of all chromosomes within the nucleus, yet also to allow accessibility to DNA for transcription, replication, recombination, and repair. Moreover, epigenetics is responsible for the expression of different sets of genes not only between different tissues, but also throughout different time points during human development. To accomplish these levels of regulation, DNA is organized with RNA and protein into a macromolecular complex known as chromatin. The basic unit of chromatin is a nucleosome, consisting of a pair of each of the four histone proteins (H2A, H2B, H3, and H4), around which 147 bp of DNA is wrapped (Kornberg, 1974; Richmond and Davey, 2003). Both DNA and histones are covalently modified to designate transcriptionally inaccessible and accessible regions, known respectively as heterochromatin and euchromatin (Campos and Reinberg, 2009). The deposition of these activating and silencing marks provides binding sites for additional chromatin modifiers that can re-localize nucleosomes through ATP hydrolysis (Hargreaves and Crabtree, 2011). The faithful orchestration of these enzymatic mechanisms is essential during development, and when dysregulated, they contribute to developmental disease and the onset of cancer.

### ***1.1.1 DNA methylation***

DNA methylation refers to the covalent addition of a methyl group to cytosine at the carbon-5 position (5mC). Most commonly associated with transcriptional silencing, the 5mC mark is abundant throughout heterochromatin and can also be deposited in CpG

islands, which are present in about 70-80% of human gene promoters (Goll and Bestor, 2005). CpG islands contain a high amount of cytosine-guanine dinucleotides, with the cytosine being methylated on both the sense and antisense DNA strand. *De novo* DNA methyltransferases (DNMT3A, DNMT3B, DNMT3L) deposit the 5mC mark on unmethylated DNA templates, while DNMT1, which primarily methylates hemimethylated templates, is considered a maintenance DNMT (Liang et al., 2002; Okano et al., 1998; Ooi et al., 2007; Yoder et al., 1997). Without a maintenance DNMT, 5mC would otherwise be passively removed upon successive rounds of DNA replication.

Recently, a mechanism has emerged for the active erasure of 5mC as well, in particular with respect to the widespread demethylation that occurs in the zygotic paternal genome, after fertilization, and the primordial germ cells, during embryogenesis (Kohli and Zhang, 2013). Ten-eleven translocation methylcytosine dioxygenases (TETs) were reported to successively catalyze the oxidation of 5mC into 5-hydroxymethylcytosine (5hmC), 5-formylcytosine, and 5-carboxycytosine (Ito et al., 2011; Tahiliani et al., 2009). The oxidized 5mC marks are then proposed to be removed through base or nucleotide excision repair processes (He et al., 2011; Kohli and Zhang, 2013).

DNA methylation induces silencing both by preventing transcription factors from recognizing their nucleic acid target sequences, and also through the recruitment of proteins containing methyl-CpG binding domains (MBDs) (Klose and Bird, 2006; Watt and Molloy, 1988). MBD proteins, in turn, may either recruit repressive chromatin remodeling complexes (e.g. MBD1-SETDB1, NuRD) or induce chromatin condensation (e.g. MECP2) themselves (Georgel et al., 2003; Sarraf and Stancheva, 2004; Zhang et al., 1999). Interestingly, the mutually exclusive MBD2 and MBD3 have differential targeting

and developmental effects within the NuRD (nucleosome remodeling and deacetylation) complex. Unlike MBD2, MBD3 does not bind 5mC, but a recent study suggests that it may instead bind 5hmC (Saito and Ishikawa, 2002; Yildirim et al., 2011).

Defects in the deposition, removal, and recognition of genomic DNA methylation contribute to both germline and acquired human disease. Developmental diseases are associated with mutations in both DNMT3B (ICF syndrome) and MECP2 (Rett syndrome) genes (Amir et al., 1999; Ehrlich et al., 2001). Moreover, the loss both of 5mC and 5hmC, due to DNMT and TET mutations respectively, are hallmarks of cancer, and the resultant decondensation of repetitive heterochromatin leads to an increase in genomic instability (Plass et al., 2013). Additionally, defective DNA methylation often contributes to the hypermethylation of CpG islands in the promoters of tumour suppressors, causing them to be silenced through the inappropriate recruitment of MBD proteins (Lai and Wade, 2011; McCabe et al., 2009).

### ***1.1.2 Covalent histone modifications***

Within the nucleosome, histones contain globular domains around which DNA wraps, and tail domains to mediate interactions with both chromatin remodeling proteins and DNA (Alberts et al., 2002). Histones carry a net positive charge due to an abundance of lysine and arginine residues which facilitate their interaction with the negatively charged phosphodiester backbone of DNA. Tail domains interact with the minor groove of DNA but are subject to covalent modifications such as acetylation and methylation which reduce the electrostatic interactions with DNA and act as a platform for other protein-protein interactions (Bannister and Kouzarides, 2011). Moreover, the collection and location of these modifications on histones and within DNA are critical for

hierarchical regulation, constituting the histone code (Strahl and Allis, 2000). Indeed genome-wide chromatin immunoprecipitation (ChIP) screens with massively parallel sequencing (ChIP-Seq) indicates that the presence of specific histone PTMs can distinguish transcriptionally accessible and inaccessible regions of the genome, such as promoters (H3K4me2/3), elongated gene regions (H3K36me3), active regulatory elements (H3K9ac, H3K27ac), constitutive heterochromatin (H3K9me3), and silenced genes (H3K27me3) (Encode Project, 2012). Additional modifications (e.g. ADP ribosylation, phosphorylation, ubiquitylation, sumoylation, deimination, histone tail clipping), as well as the incorporation of histone variants and non-coding RNA, also contribute to chromatin regulation (Bannister and Kouzarides, 2011; Moran et al., 2012; Talbert and Henikoff, 2010). In the following paragraphs, I focus the discussion on the proteins that write, read, and erase the histone acetylation and methylation marks.

Histone lysine residues are acetylated by histone acetyltransferase (HAT) enzymes (e.g. P300, PCAF, TIP60, HBO1), using acetyl-CoA as a cofactor, and the removal of this mark is catalyzed by histone deacetylases (HDACs) (e.g. HDAC1/2, SIRT2) (Kouzarides, 2007). Each nucleosomal histone subunit is capable of being acetylated and the deposition of this PTM contributes to the decondensation of chromatin by removing positive charges from lysine residues, which correlates with the reduced association of histone tails with linker DNA, fewer internucleosomal contacts, and a reduction in the higher order packaging of chromatin (Shahbazian and Grunstein, 2007). HDACs, on the other hand, are generally considered to contribute to the spread of heterochromatin silencing (Shahbazian and Grunstein, 2007). However, histone deacetylation is also necessary in advance of the deposition of additional PTMs at lysine

residues, such as histone methylation, which may themselves be active or repressive. In embryonic stem cells, for instance, NuRD is recruited to deacetylate H3K27 (via HDAC1/2), in advance of Polycomb Repressor 2 (PRC2)-mediated H3K27 methylation (via EZH2) (Reynolds et al., 2012b).

Histone lysine methyltransferases (KMTs) achieve their enzymatic activity using SET (Su(var)3-9, Enhancer of zeste, Trithorax) domains to catalyze the addition of methyl groups derived from S-adenosylmethionine to the  $\epsilon$ -amino group of lysine (Bannister and Kouzarides, 2011). Collectively, KMTs permit four binding states: unmethylated, monomethylated, dimethylated, and trimethylated lysine. SET proteins include KMTs such as MLL1-4 (modification: H3K4me1/2/3), SUV39H1 (H3K9me2/3), G9A (H3K9me1/2), SETDB1 (H3K9me1/2/3), EZH1/2 (H3K27me2/3), SETD2 (H3K36me1/2/3), NSD1 (H3K36me1/2), and SUV420H1/2 (H4K20me2/3) (Greer and Shi, 2012). DOT1L is also a non-SET KMT that methylates H3K79 following H2BK123 mono-ubiquitylation (McGinty et al., 2008; Min et al., 2003a). Conversely, histone lysine demethylation (KDM) is achieved by LSD1 (substrates: H3K4me1/2, H3K9me2) and by a family of proteins containing the Jumonji C (JmjC) domain (Shi et al., 2004; Tsukada et al., 2006). Among the JmjC demethylases, and demethylated substrates, that have been identified include JARID (H3K4me2/3), JMJD1 (H3K9me1/2/3), JMJD2 (H3K9me2/3, H3K36me2/3), JMJD3 (H3K27me2/3), UTX (H3K27me2/3), FBXL (H3K361/2), PHF8 (H3K9me1/2, H4K20me1), and PHF2 (H3K9me2, H4K20me3) (Baba et al., 2011; Greer and Shi, 2012; Lee et al., 2007; Stender et al., 2012).

Several interaction domains have been identified for the recognition of post-translational histone modifications (see Table 1-1). Bromodomains are the only known

**Table 1-1. Chromatin remodeling recognition domains for binding to chromatin that has been covalently modified by DNA methylation, histone acetylation, or histone methylation.<sup>1</sup>**

	Domain	Modification	Writer	Eraser
<i>DNA methylation</i>	MBD	5-methylcytosine	DNMT1, DNMT3A/B/L	TET1-3

<sup>1</sup> Table adapted from (Adams-Cioaba and Min, 2009; Greer and Shi, 2012; Kohli and Zhang, 2013; Kouzarides, 2007)<sup>2</sup> (Yildirim et al., 2011)<sup>3</sup> (Mansfield et al., 2011)<sup>4</sup> (Eustermann et al., 2011; Iwase et al., 2011; Zhang et al., 2010a)<sup>5</sup> (Bernstein et al., 2006; Min et al., 2003b)<sup>6</sup> (Xu et al., 2010a)<sup>7</sup> (Dhayalan et al., 2010; Qiu et al., 2012)

structure that binds acetylated lysine residues (Dhalluin et al., 1999). Histone methylation can be recognized by zinc finger domains, such as the PHD domain and the ADD domain. The structure of the PHD domain ( $C_4HC_3$  zinc finger) is variable among proteins as several binding substrates have been identified among different proteins including ING2 and BPTF (binds: H3K4me3), PYGO (H3K4me2), PHF21A (H3K4me0), and CHD4 (H3K4me0/H3K9me3) (Adams-Cioaba and Min, 2009; Mansfield et al., 2011; Shi et al., 2006). Another set of domains that recognize histone methylation include members of Royal Family, such as Tudor domains, chromodomains, WD40  $\beta$ -propeller domains, PWWP domains, MBT domains (Adams-Cioaba and Min, 2009; Qin and Min, 2014; Xu et al., 2010a). Variation among the binding substrates are observed in this group as well, including recognition of methylated H3K9 by the chromodomain of heterochromatin protein 1 (HP1), the binding of JMJD2A to H3K4me3 and H4K20me3 through its Tudor domain, and the binding of L3MBTL1 to H4K20me1/2 through its MBT domain (Adams-Cioaba and Min, 2009; Jacobs and Khorasanizadeh, 2002).

Any given nucleosome is likely to have multiple PTMs, and this crosstalk can influence the binding of chromatin regulators. For instance, the ATRX ADD domain requires both H3K4me0 and H3K9me3 (Eustermann et al., 2011; Iwase et al., 2011). In addition, many chromatin remodelers have binding domains for multiple substrates, such as P300, which contains both a Bromodomain and a PHD domain (Ragvin et al., 2004). Moreover, histone PTMs work in concert with multiple interactions to initiate further modifications. The NuRD complex, for example, binds 5mC through MBD2, H3K4me0/H3K9me3 through the PHD domain of CHD4, and DNA sequences through MTA transcription factor subunits (Lai and Wade, 2011; Mansfield et al., 2011). NuRD

subsequently catalyzes histone demethylation with LSD1, histone acetylation with HDAC1/2, and ATP-dependent nucleosome remodeling with CHD4. Thus, through the recruitment, coordination, and feedback with activating or silencing catalytic processes, accessible or inaccessible chromatin can be specified through histone PTMs.

### ***1.3 Chromatin remodeling complexes in human disease***

With DNA methylation and histone PTMs establishing activating and silencing signatures, active changes in nucleosome distribution are still required for localized processes such as transcription and also to induce changes in higher order chromatin structure. Enzymes known as ATP-dependent nucleosome remodelers accomplish this task through the use of their DEAD/H box helicase domain which hydrolyzes ATP, yielding the necessary energy to disrupt nucleosome-DNA interactions and redistribute the nucleosomes via sliding, removal, or exchange mechanisms (Hargreaves and Crabtree, 2011). In humans, 27 ATP-dependent nucleosome remodelers are known and subdivided into four major families: SWI/SNF (e.g. BRG1, ATRX), ISWI (e.g. SNF2H), CHD (e.g. CHD4), and INO80/SWR1 (e.g. SRCAP), with the majority incorporated into multiprotein complexes (e.g. NuRD) (Hargreaves and Crabtree, 2011). Like other enzymatic regulators of chromatin, most ATP-dependent chromatin remodelers have at least one binding domain (e.g. SANT, Bromodomain, PHD), which allows for an interaction with DNA and/or nucleosomes (Hargreaves and Crabtree, 2011).

Mutations in the chromatin remodeling marks responsible for depositing histone PTMs, as well as interactions with PTMs and the relocalization of nucleosomes, have long been associated in the etiologies of human developmental disease (van Bokhoven, 2011). More recently, the high-throughput screening of various cancer genomes using

next-generation screening technologies (e.g. Roche/454, Illumina/Solexa), has yielded mutations in many of these same epigenetic regulators (see Table 1-2) (Baylin and Jones, 2011; Metzker, 2010; Plass et al., 2013). These mutations target ATP-dependent nucleosome remodelers (ATRX), KMTs (EZH2, JARID1C, MLL2, NSD1), KDMs (ARID1B, JARID1C), HATs (CBP), histone kinases (RPS6KA3), DNMTs (DNMT3A/B), and proteins that interface with chromatin (BCOR, MECP2, PHF6). In some instances, the cancerous mutations are identical to germline mutations (e.g. EZH2) (Brookes and Shi, 2014). In others, (e.g. ATRX), developmental mutations appear to be hypomorphic, while cancer mutations are more frequently truncating (Jiao et al., 2011).

The dysregulation of epigenetic mechanisms is an early event in the onset of tumorigenesis (Baylin and Jones, 2011; Feinberg et al., 2006; Plass et al., 2013; Suva et al., 2013; You and Jones, 2012). These defects are somatically inherited and contribute toward widespread genomic instability that can accelerate the occurrence of additional mutagenic events (Baylin and Jones, 2011). Indeed, the global deregulation of DNA methylation is an early event in almost all tumours, including those that are benign (Feinberg et al., 2006; Suva et al., 2013). Moreover, PRC2 is commonly hyperactivated in cancer, leading to upregulation of the H3K27me3 silencing mark (Baylin and Jones, 2011). Thus, the epigenetic reprogramming that occurs during tumorigenesis takes advantage of the enzymes mediating both DNA methylation and covalent histone modification. However, some of the proteins in Table 1-2, including PHF6, lack the catalytic domains necessary for establishing such modifications, yet are still predicted to interact with chromatin through conserved binding domains. To better understand the role of such proteins in disease, additional functional characterization is required.

**Table 1-2. Chromatin remodeling proteins that are both germline mutated in developmental disease and somatically mutated in cancer.**

Gene	Function	Developmental disease	Type of tumour	Reference

<i>RPS6KA3</i>	Serine/threonine histone kinase	Coffin-Lowry syndrome	Prostate	(Clark et al., 2005; Trivier et al., 1996)

## 1.2 THE MOLECULAR GENETICS OF *PHF6*

Mutations in genes that encode chromatin remodeling proteins (e.g. *ATRX*, *JARID1C*, *MECP2*, *RPS6KA3*) are an underlying cause of many X-linked intellectual disability (XLID) syndromes (Amir et al., 1999; Chiurazzi et al., 2008; Gibbons et al., 1995; Jensen et al., 2005; Picketts et al., 1996; Trivier et al., 1996). While cognitive impairments are a defining phenotype of XLID, many of these syndromes also feature developmental abnormalities in other tissues (Stevenson et al., 2013). One such XLID is Börjeson-Forssman-Lehman syndrome (BFLS, MIM #301900), which has primarily been described in males (Gecz et al., 2006). The BFLS phenotype was first reported a half century ago (Borjeson et al., 1962) and in 1996, the responsible gene was mapped to the Xq26-27 chromosomal region (Gedeon et al., 1996; Mathews et al., 1989; Turner et al., 1989). In 2002, *PHD finger protein 6* (*PHF6*) mutations were identified as the cause of BFLS (Lower et al., 2002). More recently, *PHF6* mutations have also been identified in T-cell acute lymphoblastic leukemia (T-ALL) and acute myeloid leukemia (AML) patients (Van Vlierberghe et al., 2010; Van Vlierberghe et al., 2011). In order to better understand the contribution of *PHF6* mutations to the respective etiologies of BFLS, T-ALL, and AML, the structural and functional features of *PHF6* will first be reviewed.

### 1.2.1 *PHF6* structural features and functional studies in animal models

*PHF6* (Gene ID: 84295) consists of 11 exons and is transcribed into a 4.5 kb mRNA (see Figure 1-1A). Exons 2-10 encode a 365 amino acid (41 kDa) protein (Uniprot: Q8IWS0) (see Figure 1-1B), while exons 1 and 11 comprise the 5' and 3' UTRs respectively. Two mRNA isoforms exist in humans, with the second incorporating

A

B

**Figure 1-1. Schematic of the human *PHF6* gene structure and its protein product.**

(A) The human *PHF6* gene (Gene ID: 84295) is situated at Xq26.2 (133.51 to 133.56 Mb of the human GRCh37/hg19 assembly, February 2009). Two alternative transcripts have been identified and are shown, consisting of 11 or 10 exons respectively, indicated by the blue lines. In the first transcript (above), the 5' and 3' UTRs are encoded by exons 1 and 11 respectively. In the second transcript (below), exon 10 incorporates intron 10 and exon 11 from the first transcript, with the 3' UTR sequence remaining unchanged. Screen shot generated using the UCSC Genome Browser (Kent et al., 2002).

(B) PHF6 is a 365 amino acid protein (Uniprot: Q8IWS0). The locations of the ZaP domains (Zn knuckle followed by an atypical PHD), as well as the nuclear (NLS) and nucleolar (NoLS) localization sequences, are indicated.

intron 10 to increase the size of the 3' UTR (Lower et al., 2002). A third isoform is predicted to encode a truncated 312 amino acid version of the PHF6 protein, but its existence has not been confirmed experimentally (Gerhard et al., 2004).

The PHF6 protein is highly conserved among vertebrates, with 97.5% amino acid identity between humans and mice. Invertebrates do not have a *PHF6* homolog. Structural features of PHF6 include two nuclear localization sequences (NLSs), a nucleolar localization sequence (NoLS), and two zinc finger domains (Figure 1-1B). The localization of PHF6 to the nucleus and nucleolus has been confirmed by immunocytochemistry in NIH 3T3 cells, immunofluorescence of GFP-tagged PHF6 in HeLa cells, and by mass spectrometry profiles of the protein content within different subcellular compartments (Ahmad et al., 2009; Boisvert et al., 2012; Landais et al., 2005; Lower et al., 2002; Vallee et al., 2004). In mice, the loss of both NLSs and the NoLS results in the nuclear, but not nucleolar, localization of PHF6, suggesting the presence of additional interactions that recruit PHF6 to the nucleoplasm (Landais et al., 2005).

Structurally, the most prominent features of PHF6 are its two nearly identical zinc finger domains that are derived from a PZP motif (Perry, 2006). PZP motifs consist of PHD domain, followed by a zinc knuckle, followed by an atypical PHD domain. However, each zinc finger domain of PHF6 is a degenerate version of this structure as they consist only of the zinc knuckle and the atypical PHD (ZaP) (Todd and Picketts, 2012). In humans, ZaP domains are primarily found in proteins that regulate chromatin (e.g. MLL, BRPF, JMJD2) and are further discussed in Chapter 3 (see Figure 3-1).

To date, no *Phf6* animal knockout models have been published and only one study records its gene expression patterns during embryonic and postnatal mouse development.

In these mice, *Phf6* was observed to be ubiquitous, with particularly high expression in the brain and CNS throughout embryonic development, and more moderately during post-natal development and in adult tissue (Voss et al., 2007). *Phf6* was highly expressed in other embryonic tissues also, including the anterior pituitary at E12.5, nasal processes at E9.5 to E12.5, pharyngeal arches at E9.5, and limb buds at E12.5. In humans, *PHF6* is highly expressed in adult B- and T-lymphoid cells (Van Vlierberghe et al., 2011). Indeed, another study identified high *Phf6* expression levels in murine T-cell lymphoma (Landais et al., 2005). Thus collectively, these expression studies seem to indicate a greater requirement for Phf6 in proliferating cells than in post-mitotic cells.

While mapping *Phf6* gene expression patterns is informative, the underlying etiology of BFLS cannot be fully understood without functionally characterizing the molecular pathways within which Phf6 participates. Towards this end, PHF6 interaction studies were performed (see Chapter 3), describing its interaction with the NuRD complex, a chromatin remodeling regulator that contributes to lineage commitment (Reynolds et al., 2012a; Todd and Picketts, 2012). More recently, Phf6 was also found to interact with the Paf1 transcriptional elongation complex and be responsible for mediating neurogenesis in mice (Zhang et al., 2013). In this study, *Phf6* and *Paf1* shRNA was electroporated into mouse cerebral cortices, resulting in impaired neuronal migration between E14 and E19. Using gene expression arrays, the authors identified *Neuroglycan C/Chondroitin Sulfate Proteoglycan 5 (NGC/CSPG5)* as a commonly regulated target gene, and when the *NGC/CSPG5* transcript was electroporated into cortical tissue alongside *Phf6* shRNA, the neuronal migration phenotype was rescued (Zhang et al., 2013). Taken together, the results reported by Zhang et al. are consistent with the high

*Phf6* expression observed by Voss et al. in the embryonic brain, and the contribution of PHF6 towards neuronal migration during neurogenesis may partially account for the intellectual disability phenotype in BFLS patients.

### ***1.2.2 PHF6 mutations in Börjeson-Forssman-Lehmann syndrome***

The majority of BFLS cases described in the literature occur in males who display developmental delay within their first year after birth, with mild to severe intellectual disability becoming apparent during childhood and adolescence (Gecz et al., 2006; Turner et al., 2004). Additional features of the BFLS phenotype include large ears, coarse facial features (e.g. deep set eyes), long tapered fingers, syndactyly and shortening of the toes, gynaecomastia, truncal obesity, hypogonadism, hypotonia, and feeding problems during infancy. Some features are present at birth (e.g. hypogonadism), however other aspects of the phenotype present themselves during childhood and adolescence (e.g. coarse facial features, truncal obesity). Gynaecomastia in particular emerges during adolescence, although it is unclear if it is caused by breast tissue hyperplasia or lipomastia (Carter et al., 2009). Less common features of BFLS include microcephaly/macrocephaly, short stature, epilepsy, cleft lip and palate, hearing impairment, and hypopituitarism (Gecz et al., 2006). Two independent probands have also been diagnosed with bone marrow cancers, including Hodgkin's lymphoma and T-ALL (see Chapter 2) (Carter et al., 2009; Chao et al., 2010).

*PHF6* mutations that cause BFLS include missense mutations, nonsense mutations, and deletions (see Table 1-3). To date, no other mutations are known to cause BFLS, however not all BFLS patients have an identified *PHF6* mutation. In one cohort, for instance, *PHF6* mutations were only identified in 5/25 patients, indicating that there

could be additional BFLS loci, or more likely, that the clinical diagnosis of BFLS overlaps with other syndromes (Crawford et al., 2006).

BFLS with mild intellectual disability caused by a *de novo* *PHF6* mutation was described in one female patient (Crawford et al., 2006). In other BFLS families, female carriers were described as having mild to no intellectual disability. However, recent studies have identified *PHF6* mutations in female patients who exhibit more severe intellectual disability and a distinctive phenotype in comparison to classical BFLS features (Berland et al., 2011; Di Donato et al., 2014; Wieczorek et al., 2013; Zweier et al., 2013; Zweier et al., 2014). Features of this “female BFLS” phenotype overlap with Coffin-Siris syndrome and include sparse hair, deep set eyes, hypoplasia of the fifth digit, linear skin hyperpigmentation, and dental abnormalities (Di Donato et al., 2014). The female BFLS phenotype can be distinguished from male BFLS by the absence of truncal obesity and syndactyly occurring between the third and fifth toes, rather than between the second and third toes (Di Donato et al., 2014; Zweier et al., 2013).

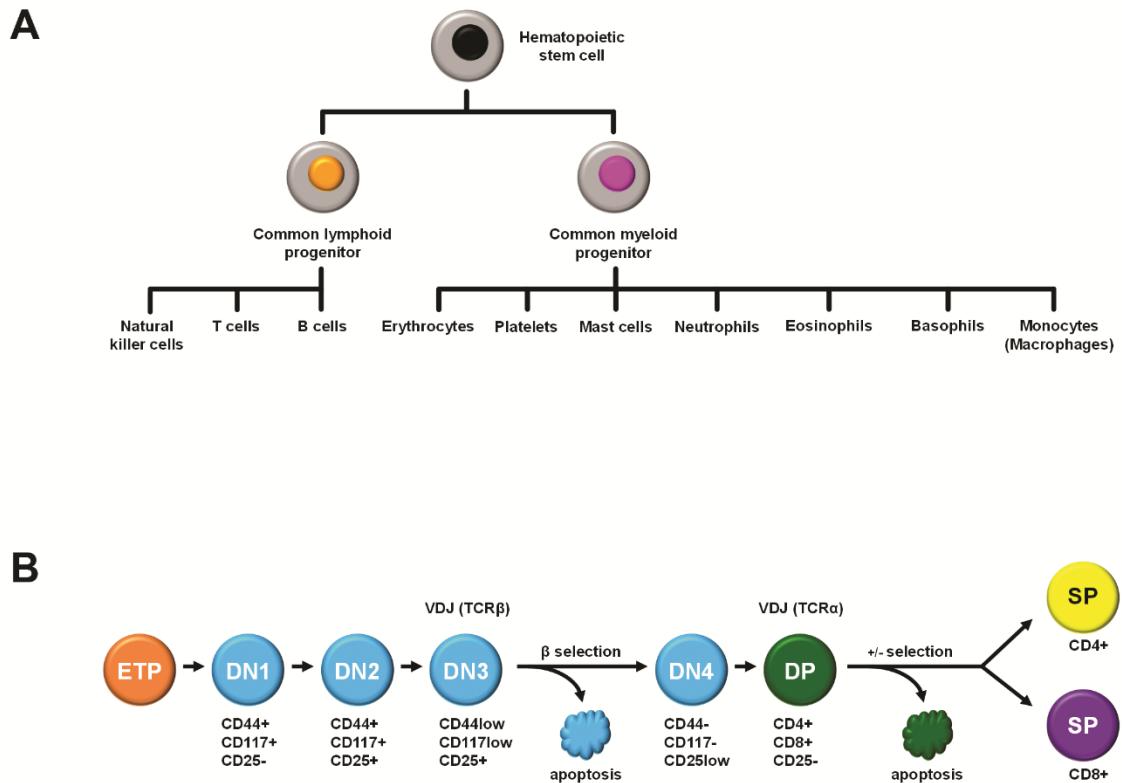

In Table 1-3, *de novo* mutations associated with the female BFLS phenotype are mostly deletions, whereas male BFLS patients more commonly have point mutations. Moreover, female carriers that lack linear skin hyperpigmentation still exhibit a phenotype that more closely resembles male BFLS than the novel female BFLS phenotype (Zweier et al., 2014). The linear skin hyperpigmentation is also a distinguishing feature between female BFLS and Coffin-Siris syndrome, and Zweier et al. argue that its presence is indicative of functional mosaicism in establishing the female BFLS phenotype (Zweier et al., 2014). In support of this claim, Zweier et al. report that

the rates of X-chromosome inactivation are variable between different tissues in patients expressing the female BFLS phenotype.

### ***1.2.3 PHF6 mutations in T-cell acute lymphoblastic leukemia***

Somatic *PHF6* mutations have also been recently identified in T-ALL (see Chapter 2) (Chao et al., 2010; Van Vlierberghe et al., 2010). Van Vlierberghe and colleagues reported *PHF6* mutations in 16% of pediatric and 38% of adult subjects. These mutations overwhelmingly consisted of deletions, frameshifts, nonsense mutations, or missense mutations that target zinc ion stabilizing residues in the second Zap domain. In four additional studies, other groups have identified T-ALL-related *PHF6* mutation frequencies varying from 5% to 40% within each cohort (Grossmann et al., 2013; Huh et al., 2013; Wang et al., 2011; Yoo et al., 2012). While Van Vlierberghe et al. reported a significantly higher incidence of *PHF6* mutations among males, significant gender differences were not observed in these later studies.

T-ALL arises in immature T-cells of the lymphoid lineage (see Figure 1-2A). During normal development (reviewed in Janeway, 2005), immature thymocytes are derived from hematopoietic progenitors migrating from bone marrow to the thymus, where they develop into immature CD4/CD8 double negative (DN), double positive (DP), and single positive (SP) thymocytes (Figure 1-2B). DN stages 1-4 can be distinguished from one another by quantifying the expression of cell surface markers (e.g. CD25, CD44, CD117) through immunophenotyping (Maecker et al., 2012). Thymocyte maturation proceeds through selection events that follow VDJ recombination of the  $\beta$  and  $\alpha$  T-cell receptors (TCRs). Failure to proceed past these checkpoints (i.e.  $\beta$  selection,  $-/+$  selection) results in apoptosis, with the surviving cells undergoing extensive proliferation.

**Figure 1-2. Schematic of hematopoiesis and thymocyte maturation.**

(A) Differentiation of the lymphoid and myeloid lineages. (B) Differentiation of  $\alpha\beta$  T cells from an early thymic progenitor (ETP) into DN (double negative,  $CD4^-CD8^-$ ), DP (double positive,  $CD4^+CD8^+$ ), and SP (single positive,  $CD4^+CD8^-$  or  $CD4^-CD8^+$ ) thymocytes. Cell surface markers for each stage are indicated. VDJ recombination of the  $\beta$  and  $\alpha$  TCR (T-cell receptor) precedes the  $\beta$  selection and positive selection events respectively. Figures adapted from (Janeway et al., 2005; Naito et al., 2011; Yui and Rothenberg, 2014).

Many of the mutations contributing to T-ALL involve oncogenic translocation events at the TCR loci and tumours are considered to be developmentally arrested when oncogenesis occurs (Van Vlierberghe and Ferrando, 2012).

T-ALL mutations are categorized in two groups: (i) those that initiate oncogenesis and define the molecular-genetic subtype of the tumour, and (ii) mutations that are recurrent (Van Vlierberghe and Ferrando, 2012). Major T-ALL subtypes are defined by aberrant oncogenic activation or chromosomal translocation events in genes coding for bHLH proteins (e.g. TAL1), LMO proteins (e.g. LMO1), homeobox proteins (e.g. TLX1, TLX3), or proto-oncogenes (e.g. c-MYB), while recurrent mutations target cell signaling pathways (e.g. NOTCH1, signal transduction), cell cycle regulatory mechanisms, and tumour suppressors (i.e. for inactivation) (Van Vlierberghe and Ferrando, 2012).

Interestingly, *PHF6* mutations are associated with tumours expressing the *TLX1* and *TLX3* oncogenes (Van Vlierberghe et al., 2010). Consistent with this observation, *PHF6* is highly expressed in DP cells, the stage at which *TLX1*-induced tumours most commonly experience developmental arrest (Ferrando et al., 2002; Van Vlierberghe et al., 2010). Moreover, *PHF6* has also been demonstrated to be a direct target for *TLX1*-mediated repression (De Keersmaecker et al., 2010). *PHF6* mutations are also co-expressed with JAK1 mutations, SET-NUP214 translocations, and activating *NOTCH1* mutations (Huh et al., 2013; Wang et al., 2011). Activating *NOTCH1* mutations occur in over half of all T-ALL patients and *PHF6* has previously been shown to be one of its downstream targets through CHIP (Palomero et al., 2006; Weng et al., 2004). Furthermore, *PHF6* is silenced by other mechanisms in T-ALL, such as oncogenic microRNAs (miR-20a, miR-26a, and miR-128-3p) and by DNA methylation in its

promoter (Kraszewska et al., 2012; Mavrakis et al., 2011; Mets et al., 2014). Collectively, these data illustrate a role for *PHF6* as a tumour suppressor during T-cell development.

#### **1.2.4 *PHF6* mutations in acute myeloid leukemia**

*PHF6* mutations have also been identified in AML patients (Van Vlierberghe et al., 2011). AML is a heterogeneous cancer that develops in multiple progenitor cell types of the myeloid lineage (see Figure 1-2A). Recent profiling of the AML cancer genome with next-generation sequencing has demonstrated that most AML mutations are recurrent, consisting primarily of chromosomal translocation events at specific loci and targeted mutations among a group of 23 genes, including epigenetic regulators such as DNMT3A, TET2, and RUNX1 (Cancer Genome Atlas Research, 2013). Van Vlierberghe et al. found *PHF6* mutations in 10/353 patients, with only one female. Similar to T-ALL, *PHF6* mutations primarily consisted of deletions, frameshifts, nonsense mutations and missense mutations targeting zinc ion-stabilizing residues from the second ZaP domain. Additional AML screens by other groups found *PHF6* mutations within 3% of screened tumours (Cancer Genome Atlas Research, 2013). Additionally, *PHF6* mutations correlated with reduced overall survival in adult patients and were observed to be co-expressed with *RUNX1* mutations (Cancer Genome Atlas Research, 2013; Patel et al., 2012). As of yet, tumours expressing *PHF6* mutations have not been correlated with any specific myeloid progenitor cell type, however *PHF6* expression levels were observed to be higher in hematopoietic stem cells and megakaryocyte/erythroid progenitors than in common myeloid progenitors or granulocyte/macrophage progenitors (Van Vlierberghe et al., 2011). It should be noted that in addition to mutations in AML, there is an isolated

report of *PHF6* mutations arising in chronic myeloid leukemia (CML) patients undergoing blast crisis (Li et al., 2013).

### ***1.2.5 Understanding how PHF6 mutations contribute to BFLS, T-ALL, and AML***

In BFLS, attempts to identify genotype-phenotype correlations between specific *PHF6* mutations and the severity of intellectual disability have not been successful (Carter et al., 2009; Zweier et al., 2014). Regardless, the distribution of mutations across the entire *PHF6* gene suggests that the phenotypes arise from a loss of PHF6 function. Given the prevalence and occurrence of common sites of PHF6 mutations in T-ALL and AML patients with those that have BFLS (e.g. R342X), it is surprising that not all BFLS patients develop leukemia. Towards this end, Chapter 2 describes a BFLS patient that acquired T-ALL.

Additionally, murine *Phf6* expression patterns (e.g. brain/CNS, embryonic limb buds) and high *PHF6* expression in human DP thymocytes correlate with the onset of BFLS and T-ALL respectively (Van Vlierberghe et al., 2010; Voss et al., 2007). To better understand the molecular mechanisms by which PHF6 may execute its function in these or other tissues, I identified PHF6 interaction partners in Chapter 3.

## 1.3 EPIGENETIC REGULATION OF rRNA SYNTHESIS IN THE NUCLEOLUS

### 1.3.1 Background

First described by Felice Fontana in 1781, the nuclear body responsible for producing the ribosomes upon which the process of translation depends was termed the “nucleolus” (meaning: little nucleus) by Gustav Valentin in 1839, as recounted by an early literature review that provided an extensive overview of nucleolar morphology across several organisms (Montgomery, 1898). Within these collected observations, many of the key properties of the nucleolus had already become apparent, including its lack of a membrane, its increased density relative to the nucleoplasm, and the dispersal of its material into chromatin when the nucleolus disappears at the onset of mitosis.

Further understanding of the reemergence of nucleoli during late mitosis occurred in 1934, when Barbara McClintock described their points of origin on mitotic maize chromosomes as nucleolar organizing bodies or regions (NORs) (McClintock, 1934). In *Drosophila*, NORs were later demonstrated to originate from DNA sites with homology to rRNA (Ritossa and Spiegelman, 1965), confirming earlier suspicions of nucleolar involvement in ribosome biogenesis (Perry, 1962). These so-called rDNA genes were found to exist as tandem repeats and in humans, are localized on the short arms of the five acrocentric chromosomes (13, 14, 15, 21, and 22) (Henderson et al., 1972), where approximately 300-400 rDNA genes occupy the region between the telomere and the centromere in a head-to-tail formation. Each rDNA gene consists of a 13.3 kb coding sequence, flanked by a 30 kb intergenic spacer (IGS) region (see Figure 1-3).

In the ensuing decades, many steps of nucleolus-mediated ribosome biogenesis

**Figure 1-3. Schematic of ribosome biogenesis.**

The rDNA coding sequence is 13.3 kb. The proximal promoter includes a core promoter element (-45/+18, C) and an upstream control element (-156/-107, U), as well as a terminator sequence (T) to which TTF-I binds. About 2 kb upstream is another RNA Pol I promoter (P'), from which pRNA is transcribed. Transcription of rRNA occurs at the FC/DFC periphery. Post-transcriptional processing is mediated by ribosomal proteins, snoRNA, and several enzymes which are responsible for packaging the immature ribosomal subunits through endo- and exonuclease cleavage, 5S rRNA incorporation (in the GC), 2'-O-ribose methylation of rRNA, pseudouridylation of rRNA, export from the nucleoplasm (Np), and finally assembly into mature ribosomes in the cytoplasm (Cp). The locations of each external transcribed spacer (ETS) and internal transcribed spacer (ITS) are indicated. Figure adapted from (Bartova et al., 2010; Haltiner et al., 1986; Henras et al., 2008; McStay and Grummt, 2008).

have been elucidated and extensively reviewed (Henras et al., 2008; Tschochner and Hurt, 2003). Ribosome biogenesis is carried out in the fibrillar centre (FC), dense fibrillar component (DFC), and granular component (GC), nucleolar subcompartments which have been defined using electron and fluorescence microscopy (Boisvert et al., 2007). To date, most data describing ribosome biogenesis has been generated from yeast models, and while there is a large degree of conservation amongst all eukaryotes, recent studies have uncovered some differences in the manner with which mammalian nucleoli process rRNA (Figure 1-3) (Mullineux and Lafontaine, 2012; Sloan et al., 2013).

In brief, ribosome biogenesis begins with the transcription of 47S pre-rRNA by RNA Polymerase I at the interface between the FC, which houses the rDNA genes and the transcriptional machinery, and the DFC, into which nascent transcripts emerge for post-transcriptional processing. 47S pre-rRNA is a polycistronic transcript from which 18S, 5.8S, and 28S rRNA are derived. In the DFC, 47S pre-rRNA is initially incorporated into a 90S pre-ribosome, then subsequently cleaved by endo- and exonucleases to liberate 18S rRNA for incorporation into the pre-40S ribosomal subunit, with 5.8S and 28S rRNA becoming incorporated within the pre-60S ribosomal subunit alongside 5S rRNA, which is transcribed by RNA Pol II and imported into the nucleolus. Further maturation of the pre-40S and pre-60S ribosomal subunits proceeds within the GC and nucleoplasm, prior to export and assembly of the mature ribosomes in the cytoplasm.

In its entirety, ribosome biogenesis requires the concerted coordination of over 200 factors (e.g. enzymes, ribosomal proteins, snoRNAs), many of which have been identified through mass spectrometry-based protein identification analyses (Henras et al., 2008). The involvement of so many factors in ribosome biogenesis necessitates a

tremendous expenditure of cellular resources (Warner, 1999). In order to conserve such resources, epigenetic regulation of the rDNA gene has emerged as an important means by which a cell can efficiently control the rate of ribosome biogenesis that it may require.

### ***1.3.2 The epigenetics of rDNA transcription***

Early investigations into the rDNA activation status utilized psoralen, which intercalates into dsDNA but not if it is associated with nucleosomes, and crosslinking, observing that coding rDNA exists in one of two states: transcriptionally accessible rDNA (nucleosome-free) and inaccessible rDNA (nucleosome-dense) (Conconi et al., 1989; Dammann et al., 1993). Further studies demonstrated that inaccessible rDNA corresponded with enhanced methylation of CpG dinucleotides in the promoter, and that the inhibition of cytosine methylation with 5-aza-2'-deoxycytidine caused an upregulation in the transcription of rDNA (Santoro and Grummt, 2001). More recently, ChIP-sequencing of rDNA genes in human cell lines identified an active chromatin signature at the rDNA promoter (e.g. H3K4me1/2/3, H3K9ac, H3K27ac) and that the active rDNA coding sequence was generally nucleosome-free (Zentner et al., 2011). Repressive chromatin marks (H3K9me1, H3K27me3, H4K20me1) were observed to have a broader distribution throughout rDNA, particularly within the IGS. Notably, Zentner et al. refer to the similarity of active chromatin signatures among their different cell models, while repressive marks exhibited more heterogeneous distribution patterns, suggesting a greater degree of functional redundancy in the mechanisms that govern rDNA repression vs. activation (see Figure 1-4).

RNA Pol I is a 14 subunit protein complex (Kuhn et al., 2007) whose sole identified function is to transcribe rDNA, consistent with its ChIP-Seq binding profile

**Figure 1-4. Epigenetic regulation of rRNA transcription.**

(A) Transcriptionally active rDNA.

(B) Transcriptionally silenced rDNA.

(Zentner et al., 2011). Like mRNA transcription, RNA Pol I-mediated transcription consists of an initiation, elongation, and termination phase (Denissov et al., 2011; McStay and Grummt, 2008; Nemeth et al., 2013; Schneider, 2012). RNA Pol I is recruited to rDNA by the pre-initiation complex (PIC), which consists of upstream binding factor (UBF) and selectivity factor (SL1) (Learned et al., 1986), as well as their collective recruitment of TIF-IA (Yuan et al., 2002). SL1 contributes to promoter recognition through its TATA-binding protein (TBP) subunit and UBF is a transcriptional activator for RNA Pol I (Bell et al., 1988). Interestingly, the activity of UBF was proposed to be mediated by its ability to outcompete linker histone H1, thereby preventing condensed chromatin from forming (Kermekchiev et al., 1997). In addition, UBF is a target for extracellular-signal-regulated kinases (ERKs) to regulate the rate of RNA Pol I transcription during elongation (Stefanovsky et al., 2006).

Interestingly, both the binding of the CTCF insulator protein between the IGS and the rDNA promoter as well as the binding of the transcription termination factor (TTF-I) to the rDNA promoter is necessary for the respective recruitment of UBF (van de Nobelen et al., 2010; Zentner et al., 2011) and activation of RNA Pol I (Langst et al., 1998). Indeed, studies into the mechanisms that underlie ribosomopathies, developmental diseases that negatively affect ribosome biogenesis, have uncovered the contributions of numerous chromatin remodeling proteins towards the transcriptional activation of rDNA, including BLM (Bloom's syndrome) (Grierson et al., 2012), CHD7 (CHARGE syndrome) (Zentner et al., 2010), CSB (Cockayne syndrome) (Bradsher et al., 2002), PHF8 (Siderius XLID) (Feng et al., 2010; Zhu et al., 2010), TCOF1 (Treacher Collins) (Valdez et al., 2004), and WRN (Werner syndrome) (Shiratori et al., 2002).

The activation of transcriptionally open rDNA is also dependent on the proper silencing of a sufficient level of the remaining rDNA repeats. Indeed the derepression of NORs correlates with an increase in genomic instability (Ide et al., 2010) and ribosome biogenesis is commonly hyperactivated in cancer (Hannan et al., 2013; Montanaro et al., 2008). Moreover, the presence of heterochromatin at the nucleolar periphery contributes to the stability of nucleolar structure and function (McStay and Grummt, 2008). One important factor in mediating the establishment of this heterochromatin (Guettg et al., 2010) is the nucleolar remodeling complex (NoRC). NoRC consists of the TTF-I-interacting protein 5 (TIP5) and the SNF2H ATPase and its role has primarily been established in the silencing of rDNA (Strohner et al., 2001; Strohner et al., 2004)

As members of NoRC, SNF2H engages in ATP-dependent nucleosome remodeling to disfavour PIC recruitment, while TIP5 is a large scaffolding subunit that engages in both the targeting of NoRC to the rDNA promoter, via its interaction with TTF-I, as well as the recruitment of additional chromatin repressors, such as DNA methyltransferases (DNMT1, DNMT3) and HDACs (SIN3 co-repressor) (McStay and Grummt, 2008; Santoro et al., 2002; Zhou et al., 2002). More recently, the association of NoRC to rDNA was found to be dependent upon an interaction with a promoter-associated non-coding RNA (pRNA) that is transcribed by RNA Pol I from an alternative promoter that is 2 kb upstream of the coding rDNA TSS (Mayer et al., 2006). The dual presence of pRNA and TIP5 has further been demonstrated to be co-operational in localizing DNMT3B (Schmitz et al., 2010) and PARP1 (Guettg et al., 2012), which poly (ADP) ribosylates DNA, to the rDNA promoter to promote silencing.

Interestingly, NoRC-mediated rDNA repression appears to be dynamic and subject to competition or reversal by other chromatin regulators. For instance, Cockayne syndrome protein B (CSB) competes with TIP5 in the binding of TTF-I, resulting in the recruitment of PCAF histone acetyltransferase to rDNA, which may counter SIN3-mediated histone deacetylation (Shen et al., 2013; Xie et al., 2012). Furthermore, CSB has been shown to interact with NuRD in the activation of rDNA (Xie et al., 2012), and NuRD additionally represses TIF5 at the transcriptional level (Ling et al., 2013). In addition, the CpG methylation deposited by NoRC may also be reversible, as evidenced by the ability of GADD45A to remove methylated cytosines at the rDNA promoter through the induction of nucleotide excision repair mechanisms (Schmitz et al., 2009).

Additional factors that participate in the regulation of rRNA synthesis continue to be identified in the literature and participate in transcriptional regulation (e.g. RUNX2) or the deposition (e.g. PRMT5), removal (e.g. JHDM1B), and reading (e.g. MBD) of chromatin marks (Ali et al., 2012; Frescas et al., 2007; Ghoshal et al., 2004; Majumder et al., 2010; Young et al., 2007). These processes act in concert to determine both whether the PIC will recruit RNA Pol I, but also maintain the ultrastructure of the NOR. Adding an additional layer of regulatory complexity, rDNA activity has also been shown to be influenced by the cell cycle and environmental stress.

### ***1.3.3 Nucleolar regulation by the cell cycle and environmental stress***

The influence of the cell cycle in mediating nucleolar structure and function is well demonstrated by its Cyclin B-CDK1-mediated disassembly during mitotic prophase and its PP1/PP2A-mediated reassembly during telophase and early G<sub>1</sub> (Hernandez-Verdun, 2011). Following reassembly, nucleolar regulation continues to be subject to cell

cycle regulation between G<sub>1</sub> and G<sub>2</sub> phase, during which rRNA synthesis is progressively upregulated in a controlled manner in preparation for cell division (Montanaro et al., 2008). In cancer, this process is accelerated through the activation of oncogenes like c-Myc to promote rRNA synthesis (Grandori et al., 2005). On the other hand, inactivating tumour suppressors like pRB and p53 act in limiting the amount of PIC that is loaded onto the rDNA promoter (Montanaro et al., 2008).

Active UBF levels positively correlate with the rate of rDNA transcription (Sanij et al., 2008). During early G<sub>1</sub>, unphosphorylated pRB binds UBF and prevents it from binding SL1 to form the PIC (Cavanaugh et al., 1995; Hannan et al., 2000; Montanaro et al., 2008). One recognized function of pRB is to mediate progression through the G<sub>1</sub>/S checkpoint (Chen et al., 2009). Through most of G<sub>1</sub>, hypophosphorylated pRB is bound to E2F transcription factors thereby preventing them from activating their target genes to favour S phase entry. However, as the cell cycle progresses towards the G<sub>1</sub>/S transition, Cyclin D and E levels are progressively induced and their associated kinases, CDK4/6 and CDK2 respectively, hyperphosphorylate pRB to release the E2Fs. Likewise, Cyclin D-CDK4 and Cyclin E-CDK2 favour the release of UBF from pRB by hyperphosphorylating these targets, resulting in the upregulation of rRNA synthesis (Montanaro et al., 2008; Voit et al., 1999).

Similar inhibition of rRNA synthesis is achieved by p53 (Bieging et al., 2014; Golomb et al., 2014). Systematic p53 turnover is regulated by MDM2, which targets p53 for proteasomal degradation under normal conditions, thereby preventing p53 from initiating cell cycle arrest or apoptosis (Haupt et al., 1997; Kubbutat et al., 1997). However during cellular stress, MDM2 becomes immobilized within the nucleolus (e.g.

via interactions with ARF and PML), releasing activated p53 which binds SL1 to prevent PIC formation, thereby repressing rDNA (Bernardi et al., 2004; Rubbi and Milner, 2003; Weber et al., 1999; Zhai and Comai, 2000). Interestingly, lncRNA transcripts expressed from the rDNA IGS region have been demonstrated to immobilize MDM2 and other proteins (e.g. VHL, HSP70, RNA Pol I subunits) in response to cellular stress (e.g. DNA damage, hypoxia, heat shock) in a recently defined nucleolar detention pathway (NoDP) (Audas et al., 2012; Jacob et al., 2013). The NoDP may partially account for the many proteins with no known nucleolar functions that have been identified from mass spectrometry-based characterizations of the nucleolar proteome (Ahmad et al., 2009).

#### ***1.3.4 PHF6 in the nucleolus***

PHF6 has an NoLS that is necessary for its localization into the nucleolus (Lower et al., 2002), but no role has so far been identified in the contribution of PHF6 towards ribosome biogenesis. The presence of PHD-like zinc finger domains in the PHF6 structure could suggest an interaction with chromatin at the NOR. Indeed, JMJD2B and G2E3, which contain similar zinc fingers, are also found in the nucleolus, but it remains unclear whether their zinc fingers are responsible for this localization (Bartova et al., 2011; Brooks et al., 2007). In Chapter 4 of the thesis, I provide further characterization of nucleolar PHF6 interactions towards the identification of its cellular function.

## 1.4 RATIONALE, HYPOTHESIS, AND SPECIFIC AIMS

The association of *PHF6* mutations with BFLS, T-ALL, AML, and CML suggests a role for PHF6 as a developmental regulator and tumour suppressor. Prior to the work presented in this thesis, *PHF6* mutations were not yet linked with T-ALL, PHF6 had no known protein interactions, and the role of nucleolar PHF6 was uncharacterized. My **overarching hypothesis** was that PHF6 functions within a protein complex to promote transcriptional regulation. Moreover, mutations in *PHF6* impair neuronal and lymphoid differentiation, resulting in BFLS or leukemia. To address this global hypothesis, I proposed the following **specific aims**:

### **1.4.1 To understand how PHF6 mutations may predispose BFLS patients to T-ALL:**

Based on the association between murine *Phf6* and T-cell lymphoma, NOTCH1-binding to *PHF6*, and the occurrence of another hematopoietic cancer (Hodgkin lymphoma) in a BFLS patient, it was **hypothesized** that *PHF6* mutations may predispose BFLS patients to T-ALL. To address this hypothesis, PCR screens were performed on BFLS and T-ALL patients.

### **1.4.2 To identify and characterize PHF6 protein interactions:**

PHF6 shares structural features with known chromatin remodeling proteins, including those that directly interact with histones, but very little was known regarding its functions or the downstream cellular processes that it regulates. Based on its zinc finger domains and its role in BFLS and leukemia, PHF6 was **hypothesized** to interact with one or more chromatin remodeling complexes that impinge upon proper development during

embryogenesis and hematopoiesis. To address this hypothesis, recombinant PHF6 was immunoprecipitated and co-eluting proteins were identified by mass spectrometry.

### **1.4.3 To identify a nucleolar function for PHF6:**

Despite observations in the literature of its strong nucleolar association, the specific role of PHF6 in the nucleolus was unknown. Because PHF6 interacted with both chromatin remodeling and ribosomal factors in the previous aim, it was **hypothesized** that PHF6 regulated rRNA synthesis at either the transcriptional or post-transcriptional level. To address this hypothesis, the localization of PHF6 to specific subnucleolar compartments was assessed by the immunofluorescent analysis of chemically disrupted nucleoli and by chromatin immunoprecipitation.

## **CHAPTER 2**

### **T-Cell Acute Lymphoblastic Leukemia in Association with Börjeson–Forssman–Lehmann Syndrome Due To a Mutation in PHF6**

## **Purpose**

To understand how PHF6 mutations may predispose BFLS patients to T-ALL.

## **Submission Information**

Submitted: 27 December 2009

## **Contribution of Co-Authors**

Matthew A.M. Todd prepared pediatric patient lymphoblast DNA for sequencing to identify *PHF6* mutations (see supplementary information on pages 45-47). Note that these supplementary data were not shown in the original publication.

Mwe Mwe Chao characterized the clinical features of the BFLS patient shown in Figure 2-1. Udo Kontny provided pediatric patient lymphoblast DNA. The manuscript was jointly written by Christian P. Kratz and David J. Picketts.

**ABSTRACT**

Börjeson–Forssman–Lehmann syndrome (BFLS) is a rare X-linked mental retardation syndrome that is caused by germline mutations in PHF6. We describe a 9-year-old male with BFLS, who developed T- cell acute lymphoblastic leukemia (T-ALL). The PHF6 gene is located on the X chromosome and encodes a protein with two PHD-type zinc finger domains and four nuclear localization sequences. Previously, overexpression of Phf6 was observed in murine T-cell lymphomas. Our observation indicates that BFLS may represent a cancer predisposition syndrome and that mutations of PHF6 contribute to T-ALL.

## INTRODUCTION

Several onco- and tumor suppressor genes that are somatically altered in cancer have also been found to be mutated in the germline of individuals with inherited conditions, supporting the notion that, at least in part, oncogenesis and embryogenesis share common pathways. Examples include germline mutations in the oncogene KRAS in patients with Noonan syndrome (Schubbert et al., 2006), germline HRAS mutations in patients with Costello syndrome (Aoki et al., 2005), and germline mutations of the tumor suppressor gene PTEN in individuals with Cowden disease (Liaw et al., 1997). Moreover, constitutional mutations have been uncovered in several leukemia-associated transcription factors such as RUNX1 (Song et al., 1999) (familial thrombocytopenia with propensity to AML) and GATA1 (congenital dyserythropoietic anemia with macrothrombocytopenia) (Nichols et al., 2000). Not surprisingly, inherited conditions that are caused by germline mutations of cancer-related genes are often associated with a spectrum of malignancies occurring at variable frequencies (Aoki et al., 2005; Liaw et al., 1997; Schubbert et al., 2006; Song et al., 1999). Patients with genetic developmental disorders who develop cancer are of scientific interest because the mutated gene underlying their condition may confer a cancer predisposition. Additionally, disease causative genes of such inherited conditions may be somatically mutated in cancer. In this regard, germline mutations of the ATRX gene are the causes of several X-linked intellectual disability syndromes while somatic mutations have been identified in patients with preleukemic alpha-thalassemia myelodysplastic syndrome (ATMDS) (Gibbons et al., 2008). Thus, the clinical description of such rare associations may have broad

implications in the understanding of cancer biology and lead to the focused identification of novel cancer genes.

**CASE REPORT AND RESULTS**

We report on a 9-year-old male with Börjeson-Forssman-Lehmann syndrome (BFLS; OMIM 301900) (Figure 1), a rare X-linked disorder associated with intellectual disability, distinctive facial features, truncal obesity, and gynecomastia, which is caused by germline mutations of PHF6, reviewed in (Gecz et al., 2006). Our patient was diagnosed with T-cell acute lymphoblastic leukemia (T-ALL) at age 7 when he presented with hyperleukocytosis and enlarged cervical lymph nodes. Flow cytometric study of bone marrow cells showed blast cells expressing CD45, CD5, CD4, CD8, CD2, CD7, CD9, CD1a, and cytoplasmic CD3 consistent with T-cell phenotype. Cytogenetic analysis of leukemia cells revealed a normal male karyotype. Treatment (high-risk arm of ANZCCSG ALL Study VII) was complicated by transient liver failure during the induction phase; however, the patient recovered and is currently receiving maintenance chemotherapy. Mutation analysis of DNA extracted from peripheral blood taken during remission showed a mutation of PHF6, NM\_032458.2: c.1024C>T, that results in a premature termination codon (p.R342X) within exon 10. Leukemia cells were not available for analysis.

**Figure 2-1. Patient with T-ALL and Börjeson–Forsman–Lehmann syndrome, 9 years.**

Note deep-set eyes, large, fleshy, posteriorly rotated ears, central obesity, breast enlargement, and tapering fingers.

## DISCUSSION

The PHF6 gene is a member of a large family of zinc-finger genes and is ubiquitously expressed. The gene product, a 365-amino-acid protein, contains four nuclear localization sequences but its function remains unknown. Expression of green fluorescent-labeled PHF6 showed subcellular localization to the nucleus and nucleolus, reviewed in (Gecz et al., 2006). The latter serves as a key organelle in the synthesis and assembly of ribosomal subunits and is linked to cell growth and proliferation. PHF6 also contains two imperfect plant homeodomain-type zinc fingers (PHD), resembling transcriptional regulators such as MLL, which is frequently disrupted by leukemia-associated translocations (Gecz et al., 2006). The data suggest a role for PHF6 as a transcriptional regulator. There are less than 30 unrelated cases of BFLS with confirmed PHF6 mutations reported in the literature. Germline mutations associated with BFLS are predominantly missense and truncation mutations in and around exons 2 and 10 (Gecz et al., 2006). The c.1024C>T (p.R342X) mutation found in our patient results in a premature termination within exon 10, affecting the 5'-CpG dinucleotide codon for the amino acid arginine which was previously identified in the original BFLS family and is a recurrent mutation in BFLS (Lower et al., 2004). Although BFLS is not recognized as a cancer predisposition syndrome, another patient with BFLS has been reported to have developed Hodgkin lymphoma (Carter et al., 2009). Interestingly, a study by Landais et al. (Landais et al., 2005) implicated Phf6 overexpression in T-cell lymphoma in mice. Specifically, the highly leukemogenic radiation leukemia retrovirus VL3 (RadLV/VL3) induced T-cell lymphoma in a murine model by retroviral integrations in c-myc, Pim1, Notch1, and Kis2 (Kaplan Integration Site 2) loci. Kis2 rearrangements occurred in 11%

of murine lymphomas and resulted in the overexpression of the nearby Phf6 gene implicating a role for Phf6 in T-cell lymphoma development (Landais et al., 2005). Moreover, in another study, comparative genomic hybridization (CGH) identified DNA imbalances in 7 of 37 (19%) human T-cell lymphoma samples from 29 patients with gains related to either the whole or part of the X chromosome that includes bands Xq26-27 containing the PHF6 gene locus (Renedo et al., 2001). Lastly, in gene expression profiling PHF6 has been identified as a direct target gene of NOTCH1, which is frequently mutated in T-ALL (Palomero et al., 2006). Murine Phf6 protein expression analysis demonstrated mild-to-moderate levels of expression of Phf6 in many adult organs including the thymus and spleen (Voss et al., 2007). Taken together, these observations suggest a role of PHF6 in T- cell ALL/lymphoma tumorigenesis. Moreover, because the gene is located on the X chromosome, this may explain the preponderance of T-ALL/lymphoma in males. Ongoing and future functional and genetic studies such as PHF6 mutation analysis in primary human T-ALL/lymphoma cells are necessary to further characterize the role of PHF6 in human cancer.

## **ADDENDUM**

In a pilot study we sequenced DNA from pediatric cases of T-ALL for somatic mutations in PHF6. We screened nine unselected patients who had been treated at the Division of Pediatric Hematology and Oncology, Department of Pediatrics and Adolescent Medicine, University of Freiburg, Germany. Notably, in blast cells from one male pediatric patient with T-ALL we found a novel mutation of PHF6 (NM\_032458.2: c.987T>A) predicting a p.H329Q substitution. After submission of this article, a report from Van Vlierberghe and colleagues described somatic mutations and deletions of PHF6 in patients with T-ALL (Van Vlierberghe et al., 2010).

## **SUPPLEMENTARY INFORMATION**

### **SUPPLEMENTARY MATERIALS AND METHODS**

#### ***PHF6 patient mutation analysis***

Lymphoblast DNA samples from nine pediatric patients affected with T-ALL (Division of Pediatric Hematology and Oncology, Department of Pediatrics and Adolescent Medicine, University of Freiburg, Germany) were screened for somatic PHF6 mutations. Genomic DNA from the affected individuals was used to amplify each exon of the PHF6 gene with forward and reverse primers that annealed to flanking intron sequences, with genomic DNA from an unaffected individual representing a control for each PCR reaction. Exons 2+3 were amplified in a single product, as were exons 4+5 and exons 6+7. For each PCR reaction, 100 ng of template DNA was amplified over 30 cycles, then submitted to the laboratory of Dr. Dennis Bulman for DNA purification and sequencing. For primer sequences and the annealing temperatures used, see Table 2-S1. Sequence files were processed and annotated with Applied Biosystems Sequence Scanner v1.0 software, and alignments with wild type PHF6 cDNA were performed using the NCBI BLAST algorithm (<http://blast.ncbi.nlm.nih.gov/Blast.cgi>) to identify mutations.

### **SUPPLEMENTARY RESULTS**

Figure 2-S1 presents the data described in the Chapter 2 Addendum section. DNA from the blast cells of a male pediatric T-ALL patient contained a novel c.987T>A mutation in the *PHF6* gene (Figure 2-S1A). This mutation is predicted to cause a p.H329Q missense mutation in the protein, resulting in the loss of a key zinc ion stabilizing histidine residue in the second ZaP domain (Figure 2-S1B, C).

**ABSTRACT**

Mutations in *PHF6* are the cause of Börjeson-Forssman-Lehman syndrome (BFLS), an X-linked intellectual disability (XLID) disorder, and both T-cell acute lymphoblastic leukemia (T-ALL) and acute myeloid leukemia (AML). The *PHF6* gene encodes a protein with two PHD-like zinc finger domains. As many PHD-like domains function to target chromatin remodelers to post-translationally modified histones, this suggests a role for PHF6 in chromatin regulation. However, PHD domains are usually found in association with a catalytic domain, a feature that is lacking in PHF6. This distinct domain structure and the minimal information on its cellular function prompted us to perform a proteomic screen to identify PHF6 binding partners. We expressed recombinant Flag-tagged PHF6 in HEK 293T cells for co-immunoprecipitation, and analyzed the purified products by mass spectrometry. We identified proteins involved in ribosome biogenesis, RNA splicing, and chromatin regulation, consistent with PHF6 localization to both the nucleoplasm and nucleolus. Notably, PHF6 co-purified with multiple constituents of the Nucleosome Remodeling and Deacetylation (NuRD) complex, including CHD4, HDAC1, and RBBP4. We demonstrate that this PHF6-NuRD complex is not present in the nucleolus but is restricted to the nucleoplasm. The association with NuRD represents the first known interaction for PHF6 and implicates it in chromatin regulation.

## INTRODUCTION

PHF6 is a ubiquitously expressed 41 kDa protein that is conserved and vertebrate-specific. In mouse, Phf6 is predominantly expressed in the brain, central nervous system, and a number of embryonic tissues including the pharyngeal arches, nasal processes, anterior pituitary, and limb buds (Voss et al., 2007). In humans, PHF6 is most highly expressed in the thymus, with moderate expression in thyroid, ovary, testis, and adipose tissue (Van Vlierberghe et al., 2010). Structurally, PHF6 possesses two PHD-like zinc fingers and localization sequences for the nucleus and nucleolus (Lower et al., 2002).

PHD-like zinc fingers are common structural components of chromatin remodeling proteins, serving as epigenetic reader domains that interact with post-translationally modified histones. For instance, the PHD domains of Bromodomain and PHD Finger-containing Transcription Factor (BPTF) and Inhibitor of Growth 2 (ING2) bind to H3K4me3, while the PHD domains of Chromodomain-Helicase-DNA-binding protein 4 (CHD4) bind to H3K4me0/H3K9me3, indicating that there is a degree of variability to the post-translational modifications that are recognized by different PHD domains (Li et al., 2006; Mansfield et al., 2011; Shi et al., 2006). Along with other chromatin reading domains, PHD fingers facilitate the targeting of chromatin remodeling proteins to specific genomic loci to regulate gene expression and chromatin structure by engaging enzymatic mechanisms that involve DNA methylation, covalent histone modifications, and the ATP-dependent relocation of nucleosomes. Not surprisingly, genetic mutations in chromatin remodeling proteins have been identified as a cause of human developmental disease, including X-linked intellectual disability (XLID) disorders (e.g. ATRX, MECP2) (Amir et al., 1999; Gibbons et al., 1995).

**Figure 3-1. PHF6 is a PHD-like zinc finger protein that is mutated in BFLS and T-ALL.**

(A) Schematic of the PHF6 protein detailing its two C<sub>2</sub>H<sub>2</sub> zinc knuckles (ZK) with an atypical PHD domain (PHD), that we collectively term the ZaP domain. PHF6 also has two nuclear localization sequences (green) and a nucleolar localization sequence (yellow). Known point mutations for BFLS (Chao et al., 2010; Gez et al., 2006; Mangelsdorf et al., 2009), T-ALL (Chao et al., 2010; Van Vlierberghe et al., 2010; Wang et al., 2011; Yoo et al., 2012), and AML (Van Vlierberghe et al., 2011; Yoo et al., 2012) are shown in relation to the structural features of PHF6. Closed circles represent frameshift and/or truncating mutations, while open circles indicate missense mutations or single amino acid deletions. (B) An alignment of the ZaP domain from human proteins using the ClustalW 1.83 algorithm (Thompson et al., 1994). Zinc ion-stabilizing cysteine (blue) and histidine (green) residues are indicated. Additional conserved residues are highlighted in yellow. Amino acid positions are indicated.

(“\*” = identical, “.” = conserved substitution, “:” = semi-conserved substitution)

Mutations in *PHF6* (Figure 3-1A) cause BFLS (Lower et al., 2002), an XLID disorder further characterized by truncal obesity, gynaecomastia, hypogonadism, facial dysmorphism, digit abnormalities, hypogonadism, and large ears (Gecz et al., 2006). We have reported upon BFLS patients that have also developed bone marrow cancers (Carter et al., 2009; Chao et al., 2010), and more recently, somatic mutations of *PHF6* have been found in patients with T-ALL (Van Vlierberghe et al., 2010) and AML (Van Vlierberghe et al., 2011). Mutations within *PHF6* are located throughout the gene and include missense, nonsense, frameshift, and small deletion alterations. One striking difference is that leukemic *PHF6* mutations predominantly result in a frameshift or truncation whereas BFLS mutations are largely missense changes. Moreover, *PHF6* has been shown to be inactivated by DNA methylation and miRNA silencing in T-ALL (Kraszewska et al., 2012; Mavrakis et al., 2011).

Other than its similarity to chromatin-interacting proteins and its subnuclear localization, very little is known about the functional role of *PHF6* or the pathophysiological mechanism underlying *PHF6* mutations. To address this lack of knowledge, we sought to identify *PHF6* interacting proteins by co-immunoprecipitation coupled with mass spectrometry identification. Here, we present our findings that *PHF6* is a novel interactor with the NuRD complex and that *PHF6* also co-purifies with histones, ribosomal assembly subunits, and multiple nucleolar proteins. The *PHF6*-NuRD complex was enriched in the nucleoplasm, suggesting that distinct *PHF6* complexes define functionally specific roles in the nucleoplasm and nucleolus. Moreover, these findings confirm a role for *PHF6* in modifying chromatin structure and suggest a general function in gene regulation.

## MATERIALS AND METHODS

### *Generation of plasmid constructs*

A cDNA fragment comprising the entire *PHF6* ORF was amplified from a pEGFP-C3-*PHF6* expression plasmid (Vallee et al., 2004) using the following primers: *PHF6*-EcoRI-Fwd (5'-gctgaattcatgtcaagctcagttg-3'), and *PHF6*-XhoI-Rev (5'-gctctcgaggtttccattaagttg-3'). PCR products were purified and digested with EcoR I and Xho I, then directionally cloned into the pBRIT-LoxP-NTAP and pBRIT-LoxP-CTAP retroviral plasmid vectors (Figure 3-3A), which have been previously described (McKinnell et al., 2008). For each vector, *PHF6* was cloned in-frame with a TAP tag, which consists of a 6X His tag, a tobacco etch virus (TEV) sequence, and a 3X Flag tag. Protein expression is driven by a cytomegalovirus (CMV) promoter, and the vector contains resistance genes for puromycin and ampicillin. pBRIT-LoxP-NTAP vector was used as an empty vector control.

### *Cell culture*

HEK 293T cells were cultured in DMEM (Dulbecco's Modified Eagle Medium), supplemented with 10% FBS (fetal bovine serum) and 1% penicillin-streptomycin (Invitrogen). Expression plasmids were transfected into HEK 293T for 6 hours with Lipofectamine 2000 (Invitrogen) according to the manufacturer's protocol. Following transfection, cells were allowed to recover for 24 hours, then stably selected for expression with 1.5  $\mu\text{g}/\mu\text{L}$  puromycin (Sigma) for 2 weeks prior to colony selection. *PHF6* expression in each clone was assessed by Western blot, and cell lines derived from the colonies were cultured in selection media for all subsequent experiments.

### ***Antibodies***

See Table 3-S1 for information regarding primary and secondary antibodies.

### ***Immunocytochemistry***

HEK 293T cells were trypsinized and washed with PBS on ice prior to cytocentrifugation using the Cytospin system (Thermo Shandon). Approximately 15 000 cells were applied per slide following centrifugation at 800 g for 5 minutes. Cells were then fixed for 10 minutes on ice in 2-4% paraformaldehyde in either PBS or CSK (10 mM PIPES pH 6.8, 10 mM NaCl, 300 mM sucrose, 3 mM MgCl<sub>2</sub>, 2 mM EDTA) buffer, then washed with PBS before permeabilizing for 10 minutes with 0.5% Triton X in PBS at room temperature. For blocking, cells were incubated for 1 hour at room temperature in PBS with 20% horse serum and 0.5% FBS. Primary antibodies were incubated overnight at 4°C in a humidified box using the appropriate antibody dilution (Table 3-S1) in PBS. Secondary antibodies were applied at a 1:4000 dilution (in PBS) for 40 minutes at room temperature. To visualize chromatin, cells were incubated with 100 ng/mL DAPI (in PBS) for 3 minutes prior to mounting with DAKO Fluorescent Mounting Medium. Fluorescent images were obtained using an Imager M1 microscope (Zeiss) and processed with AxioVision version 4.6 software (Zeiss).

### ***Cell fractionation***

Cytoplasmic, nuclear, and nucleolar lysates were isolated from HEK 293T cells by adapting a previously described method (Chamousset et al., 2010b). Briefly, adherent HEK 293T cells (90-95% confluency) were scraped from 10 x 15 cm plates, washed in PBS, resuspended in 10 mL of buffer A (20 mM Tris-HCl pH 7.8, 1.5 mM MgCl<sub>2</sub>, 5 mM KCl, 0.5 mM DTT), and incubated at 4°C for 15 minutes. NP-40 was then added to a

final concentration of 0.15%, and the lysate was incubated for an additional 15 minutes. The cytoplasmic and nuclear protein fractions were then collected as described, adjusted by adding 5X RIPA (250 mM Tris HCl pH 7.8, 750 mM NaCl, 5% NP-40, 2.5% sodium deoxycholate, 0.5% SDS) or 2X buffer B to a final concentration of 1X, followed by centrifugation at 15 000 g for 30 minutes to remove insoluble protein. The nucleolar pellet was isolated as described and resuspended in 1 mL buffer B (20 mM Tris-HCl pH 7.8, 1.5 mM MgCl<sub>2</sub>, 400 mM NaCl, 25% glycerol, 5 mM Na-citrate, 10 μM ZnCl<sub>2</sub>), sonicated (6 x 10 second pulses, 30% amplitude), incubated at 4°C for 30 minutes, and centrifugated at 15 000 g for 30 minutes to pellet insoluble protein.

#### ***Glycerol density gradient sedimentation***

Protein from nuclear and nucleolar fractionated lysates was separated by glycerol density gradient sedimentation according to a previously described protocol (Lessard et al., 2007). Nuclear and nucleolar fractionated lysates (1 mg each) were diluted in HEM buffer (37.5 mM HEPES-KOH pH 7.8, 50 μM EDTA, 6.25 mM MgCl<sub>2</sub>, 100 mM KCl, 0.75 mM DTT) with the glycerol concentration reduced to 10% in a final volume of 3 mL that was then layered over a 10 mL 10-30% glycerol gradient of HEM buffer. Samples were ultracentrifugated at 32 000 rpm for 20 hours at 4°C in an SW 41 Ti Beckman Coulter rotor and fractions (500 μL each) were collected from the top (#1) to the bottom (#23). Fractions were then concentrated by centrifugal filtration (MWCO 10 kDa Microcon, Millipore), with equal volumes analyzed by SDS-PAGE.

#### ***Immunoprecipitation***

HEK 293T nuclei were harvested as described for cell fractionation. After incubation with buffer A (with 0.15% NP-40), nuclei were pelleted and given an

additional 10 mL wash in the hypotonic buffer. Re-pelleted nuclei were then homogenized in 5 mL of buffer B, sonicated, incubated at 4°C for 30 minutes, and centrifugated at 3 000 g for 30 minutes to remove insoluble protein, then diluted 1:10 in binding buffer (20 mM Tris-HCl pH 7.8, 1.5 mM MgCl<sub>2</sub>, 137 mM NaCl, 10% glycerol, 5 mM Na-citrate, 10 μM ZnCl<sub>2</sub>). Input for the 3X Flag immunoprecipitations (IPs) for purification and mass spectrometry varied from 20-30 mg per experiment, but was always equivalent for the empty vector, PHF6-NTAP, and PHF6-CTAP samples. For the validation of PHF6 interactions by endogenous IPs, the input was 1-7 mg per experiment. For both pre-clearing and endogenous IPs, 1 μg of mouse/rabbit IgG or antibody and 10 μL of pre-blocked Protein G-agarose (mouse, Santa Cruz)/Protein A-sepharose (rabbit, GE Healthcare) 25% slurry was applied for every 1 mg of lysate, and all washes were performed in binding buffer. When pre-clearing, the IgG and bead slurry incubations were each performed at 4°C for 1 hour. For the endogenous IPs, antibodies were incubated with the lysate at 4°C for 16 hours, followed by incubation with the bead slurry for 1 hour. The beads were then given 5 x 10 minute washes with 1 mL of binding buffer. Proteins were eluted by applying a 1:1 mixture of binding buffer and 4X Novex loading buffer (Invitrogen) to the beads, and incubating at 100°C for 5 minutes. Equal volumes for each sample were analyzed by SDS-PAGE.

For the 3X Flag IPs, 150 μL of 50% M2-Flag agarose (Sigma) bead slurry was added to each pre-cleared lysate and incubated for 16 hours at 4°C. The beads were then given 5 x 10 minute washes with 1 mL of binding buffer. Elution was achieved using 3X Flag peptide (Sigma) competition (1st wash: 400 μg/mL in 400 μL binding buffer at 4°C for 16 hours; 2nd-5th washes: 200 μg/mL in 200 μL binding buffer at 4°C for 30

minutes). The combined elution volumes were then concentrated by centrifugal filtration, with equal volumes for each sample loaded onto the SDS-PAGE gel for band identification and extraction for mass spectrometry.

### ***Western blotting***

Cell lysates, 3X Flag IP products, endogenous IP products, or glycerol density gradient fractions were resolved by SDS-PAGE (4-12% Bis-Tris Novex gel, Invitrogen) and transferred onto PVDF membranes (Millipore). Membranes were blocked in 1X TBST with 5% milk for 2 hours at room temperature, then incubated with primary antibody overnight at 4°C in 1X TBST with 5% BSA. Following three 10 minute 1X TBST washes, membranes were incubated with secondary antibody in blocking solution for 45 minutes at room temperature. Development of the membranes was achieved using enhanced chemiluminescence (GE Healthcare) and an SRX-101A (Raytech) film developer. Consult Table 3-S1 for appropriate antibody concentrations.

### ***Mass spectrometry***

3X Flag products were resolved by 4-12% SDS-PAGE gel and stained by colloidal blue Coomassie (Invitrogen). Gel slices containing protein were manually excised and submitted to the McGill University and Génome Québec Innovation Centre for reduction, cysteine-alkylation, and in-gel tryptic digestion using an automated MassPrep workstation (Micromass), as previously described (Wasiak et al., 2002). Extracted peptides were injected onto a 300 µm x 5 mm Zorbax C18 trapping column and subsequently resolved on a 10 cm x 75 µm PicoFrit column packed with 5 µm BioBasic C18 beads. Using an Agilent 1100 series HPLC (Agilent Technologies), peptides were eluted from the column using a 30 minute gradient of 10-95% acetonitrile containing

0.1% formic acid at a flow rate of 200 nL/min, and electrosprayed upon exit from the column.

Mass spectrometric data were acquired on a QTRAP 4000 (SCIEX/ABI) using the Information Dependent Analysis (IDA) feature of Analyst 1.4.1 software (ABI). Precursor ion selection for subsequent tandem MS fragmentation analysis was done using predefined IDA criteria. Briefly, up to three doubly, triply or quadruply charged ions of intensity greater than  $2 \times 10^6$  counts per second from each enhanced-MS survey scan were selected for passage into a collision cell. Collision-induced dissociation was facilitated by collision with nitrogen gas; fragment ions were trapped in Q3 and scanned. Three enhanced-product ion scans (EPI) at a speed of 400 amu/second from 70 m/z to 1700 m/z were averaged for each selected precursor ion. Accumulation time used for EPI scans was 20 ms with Q0 trapping activated. Peak lists were generated using Distiller version 2.3.2.0 (Matrix Science) software with peak picking parameters set at 1 as for Signal Noise Ratio (SNR) and at 0.3 for Correlation Threshold (CT).

The peak-listed data was then searched against a copy of the Universal Protein Resource (UniProt) database (version: September 17, 2010) by using MASCOT version 2.3.01 (Matrix Science) and X! Tandem version 2007.01.01.1 (Global Proteome Machine). MASCOT and X! Tandem were set up to search the *Homo sapiens* (taxon ID 9606) database (88352 entries) assuming the digestion enzyme as trypsin with the maximum number of missed cleavages set at 1. MASCOT and X! Tandem were searched with a fragment ion mass tolerance of 0.80 Da, a parent ion tolerance of 1.5 Da, with the iodoacetamide derivative of cysteine specified as a fixed modification, and with methionine oxidation set as a variable modification. In X! Tandem, pyro-glutamine and

asparagine deamidation were also set as variable modifications. Scaffold version 2.06.02 (Proteome Software) was used to validate the MS/MS based peptide and protein identifications. Peptide identifications were accepted if they could be established at greater than 95% probability as specified by the Peptide Prophet algorithm (Keller et al., 2002). Protein identifications were accepted if they could be established at greater than 95% probability and contained at least 1 identified peptide. Protein probabilities were assigned by the Protein Prophet algorithm (Nesvizhskii and Aebersold, 2004). Annotated tandem mass spectra for protein identifications based on a single peptide assignment are provided in Figure 3-S1.

## RESULTS

### *PHF6 has two atypical PHD zinc fingers which represent a conserved motif*

PHD domains have been shown to interact with different histone lysine methylation marks, which are partially attributed to the variation in these domains. The canonical PHD domain is a C<sub>4</sub>HC<sub>3</sub>-type zinc finger (Aasland et al., 1995), which is capable of stabilizing two zinc ions to create protein-protein interaction surfaces (Capili et al., 2001). Variations of the PHD finger include the ADD domain (Aapola et al., 2000), which consists of a C<sub>2</sub>C<sub>2</sub> GATA finger followed by a C<sub>4</sub>C<sub>4</sub> atypical PHD finger, and the PZP motif (Perry, 2006), which consists of a canonical PHD finger followed by a C<sub>2</sub>HC zinc knuckle and a C<sub>4</sub>HC<sub>2</sub>H atypical PHD zinc finger.

To further characterize the PHF6 zinc finger domain, we performed alignments using the ClustalW algorithm (Thompson et al., 1994). We found the two zinc fingers of PHF6 to be nearly identical and that both domains correspond to a degenerate version of the PZP motif, possessing only the C<sub>2</sub>HC zinc knuckle and the C<sub>4</sub>HC<sub>2</sub>H atypical PHD, which we refer to as the ZaP domain. We subsequently performed alignments to identify all human proteins that possess a ZaP domain (Figure 3-1B) and observed that PHF6 shares homology with several chromatin remodeling proteins, including members of histone acetyltransferase complexes (BRPF1-3, JADE1-3), histone methyltransferases (MLL1-4), histone demethylases (JMJD2A-C), an E3-ubiquitin ligase (G2E3), and transcription factors (RAI1, TCF20). Additional proteins that were aligned (PHF7, PHF11, PHF14) remain uncharacterized. Unlike the PHD and ADD domains, the functional role of the ZaP domain is unclear. Nonetheless, we predicted that the presence of two ZaP domains in PHF6 was indicative of its participation in a chromatin

remodeling/transcriptional regulation complex and subsequently proceeded to further characterize the protein by identifying its interaction partners.

***PHF6 is expressed equally in the nucleoplasm and nucleolus of HEK 293T cells***

Prior to purifying PHF6 from HEK 293T cells, we assessed its expression levels and subcellular localization in this model cell line. The PHF6 protein contains nuclear and nucleolar targeting sequences and we have previously reported upon the nucleolar concentration of overexpressed GFP-tagged PHF6 in HeLa cells (Vallee et al., 2004). Consistent with this, large-scale mass spectrometry analyses of the nucleolar proteome in immortalized human cell lines have also identified PHF6 peptides in the nucleolus (Ahmad et al., 2009). Nonetheless, quantitative comparisons of nucleolar vs. nucleoplasmic PHF6 have not been performed in any model. Thus, we performed cellular fractionation to isolate cytoplasmic, nucleoplasmic, and nucleolar protein fractions from HEK 293T cells, which were analyzed by western blot (Figure 3-2A; Figure 3-S2). It is evident that most of the PHF6 protein is found in the nucleoplasm, with a significant level also present in the nucleolus and only trace amounts in the cytoplasm. Similarly, the presence of both nucleoplasmic and nucleolar PHF6 was observed qualitatively by immunocytochemistry, as shown in Figure 3-2B. Further subcellular localization analyses revealed that the expression levels of nuclear and nucleolar PHF6 remained unchanged relative to one another during the cell cycle, except during mitosis, where PHF6 fails to co-localize with chromatin until telophase (Figure 3-S3A,B). Because PHF6 is primarily localized to nuclear compartments, we restricted the purification of PHF6 interactors to nuclear lysates.

**Figure 3-2. PHF6 is localized primarily to the nucleoplasmic and nucleolar cell fractions.**

(A) Cell lysates were isolated from HEK 293T cells and fractionated into cytoplasmic protein (CP), nuclear protein (NP), and nucleolar protein (NoP). Equal amounts of protein from each fraction (10  $\mu$ g) were separated by SDS-PAGE and immunoblotted with anti-PHF6 for a comparative analysis of PHF6 expression. Antibodies for  $\alpha$ -tubulin, lamin A/C, and fibrillarin were used as control markers for the CP, NP, and NoP fractions respectively. Additional subcellular fractionation controls are presented in Figure 3-S2. (B) HEK 293T cells were immunofluorescently stained with antibodies to PHF6 (green) and nucleolin (red). Cells were counterstained with DAPI to visualize nuclei. PHF6 localizes to both the nucleoplasm and nucleolus (merge). This image is representative of all non-mitotic cells.

***Novel PHF6 binding partners were identified by co-immunoprecipitation***

To identify PHF6 interaction partners, we subcloned the coding sequence of *PHF6* cDNA into the respective multiple cloning sites of the pBRIT-LoxP-NTAP and -CTAP vectors, which have previously been used to identify Pax7 and Smn interacting partners (McKinnell et al., 2008; Shafey et al., 2010). A schematic of the PHF6 fusion proteins containing a tandem affinity purification (TAP) tag (6X His, tobacco etch virus cleavage site, 3X Flag) is presented in Figure 3-3A. PHF6 was tagged at both the N- and C-terminal ends as a precaution against mislocalization or impaired interactions of either fusion protein. The fusion proteins were stably expressed in HEK 293T cells using puromycin selection following transfection, with empty NTAP vector transfections serving as a negative control. A total of 16 PHF6-NTAP and 21 PHF6-CTAP clones were selected and analyzed for expression by western blot (Figure 3-S4). The clones showed variable levels of expression and two clones with expression levels equal to or lower than endogenous PHF6 protein levels were chosen for further analysis and purification (Figure 3-3B). Consistent with endogenous expression, the expression of the PHF6 fusion proteins was confined to the nucleus and nucleolus, as shown by immunofluorescence using a Flag antibody (Figure 3-3C).

To identify novel interacting proteins, we immunoprecipitated PHF6 fusion proteins from nuclear lysates using Flag purification, with the products of the purification separated by 4-12% gradient SDS-PAGE and visualized by colloidal Coomassie staining (Figure 3-4A). A band migrating just below M2-Flag heavy chain IgG and corresponding to the PHF6 fusion protein was visible in the PHF6-NTAP and -CTAP lanes but not the empty vector lane. Additional bands corresponding to proteins co-eluting with the PHF6

**Figure 3-3. Recombinant PHF6-TAP was stably expressed in HEK 293T cells and was localized to both the nucleus and nucleolus.**

(A) Schematic diagram of the pBRIT-LoxP-NTAP and pBRIT-LoxP-CTAP TAP-tag vectors used to express the PHF6 cDNA. For each construct, the 3X Flag tag was used for purification. (B) Immunoblots for PHF6 and Flag demonstrating transgene expression after both transient and stable transfection into HEK 293T cells. Endogenous PHF6 has a molecular weight of 41 kDa, while recombinant PHF6 has a molecular weight of 47 kDa. (C) Immunocytochemistry was performed on stable HEK 293T cell lines expressing empty vector, PHF6-NTAP, or PHF6-CTAP using antibodies for PHF6 and Flag. Flag was found to co-localize with nuclear and nucleolar PHF6 in cell lines expressing exogenous PHF6-TAP, but was absent in the cell line expressing only the empty vector.

fusion proteins, but not the empty vector, are also identified in Figure 3-4A (labeled #1-4), and gel slices corresponding to these bands, including the PHF6 gel slice (band 2), were excised and submitted for tryptic digestion and mass spectrometry analysis for protein identification. Equivalent gel slices were also excised from the empty vector control lane to allow for background subtraction. It should be noted that PHF6 was purified following TAP purification but the His tag purification conditions were too stringent to preserve many of the interactions obtained by Flag-purification alone (see Appendix A).

From this analysis, we identified 15 peptides corresponding to PHF6 observing >50% sequence coverage. Proteins that uniquely co-purified with both PHF6-NTAP and -CTAP, but not the empty vector, are presented in Table 3-1. They included histones, splicing factors, 40S ribosomal proteins, 60S ribosomal proteins, and several other nucleolar proteins consistent with the nucleolar distribution of PHF6. Of most interest was the identification of multiple components of the Nucleosome Remodeling and Deacetylation (NuRD) complex. In this regard, the highest score (1453) and most peptides (27) were attributed to CHD4. Additional identified constituents of NuRD included CHD3 (396, 8), RBBP4 (295, 5), and RBBP7 (224, 4). We also identified two peptides for MBD3, another NuRD subunit, however this data was excluded due to low confidence scores (data not shown). The identification of multiple constituents of the NuRD complex strongly suggests that PHF6 interacts with this chromatin remodeling complex. Moreover, since the NuRD complex is known to be critically involved in both development and hematopoiesis, key features associated with *PHF6* mutations, we selected this interaction for further validation and characterization.

**Figure 3-4. PHF6 co-purifies with core constituents of the NuRD complex.**

(A) Colloidal Coomassie stained gel of Flag-IP purified proteins. Purified products present in the PHF6-NTAP and PHF6-CTAP eluates, but not the empty vector, were isolated and subject to mass spectrometry (bands #1-4). PHF6-TAP is present in band #2. Equivalent gel slices from the empty vector purification were also submitted to allow for the subtraction of background peptides. (B) Analysis of Flag-IP products by immunoblotting with antibodies for PHF6, RBBP4, CHD4, HDAC1, and mSIN3A. Input represents approximately 0.05% of the Flag-IP protein lysate. Flag-IP products represent 5% of the total recovered product following immunoprecipitation. (C) Endogenous IPs were performed in untransfected HEK 293T cells using antibodies for PHF6, RBBP4, and HDAC1. The PHF6 IP was analyzed by immunoblotting with anti-CHD4 and anti-RBBP4, with the input representing 0.14% of the protein lysate. RBBP4 and HDAC1 IPs were analyzed by immunoblotting with anti-PHF6, with the input representing 1% of the protein lysate. IgG-IPs were also performed as a negative control.

***PHF6 co-purifies with the NuRD complex, but not SIN3A***

To validate the interaction between PHF6 and NuRD, we performed western blots of Flag-purified PHF6-NTAP, PHF6-CTAP, and empty vector following co-immunoprecipitation (Figure 3-4B). Illustrating the specificity of the Flag pull down, abundant amounts of exogenous PHF6 were detected, but endogenous PHF6 was not pulled down suggesting that PHF6 does not function as a dimer. The immunoblots also clearly demonstrate that CHD4 and RBBP4 are able to co-purify with both N- and C-terminally Flag-tagged PHF6, but not with immunoprecipitation by Flag alone, indicative of the specificity for the purification of NuRD with PHF6.

HDAC1, which interacts with RBBP4 as part of the core HDAC sub-complex within NuRD, also co-immunoprecipitated with PHF6. Interestingly, the core HDAC complex is known to associate with other co-repressing chromatin remodeling complexes, including SIN3 (Silverstein and Ekwall, 2005). However, our western blots indicated that mSIN3A does not co-purify with PHF6, further confirming the specificity of the association between PHF6 and NuRD.

To further confirm the interaction, we performed co-immunoprecipitations of endogenous PHF6, RBBP4, and HDAC1 from the nuclear lysates of untreated HEK 293T cells. As shown in Figure 3-4C, RBBP4 is pulled down in abundance with the PHF6 antibody, while IgG alone did not pull down the protein. Likewise, PHF6 is detected in the reciprocal pull down with RBBP4, albeit in a lesser amount, which may reflect either the relatively small proportion of RBBP4 that interacts with PHF6 or the inefficiency of the monoclonal RBBP4 antibody used for immunoprecipitation. Similarly, we could detect a weak interaction of endogenous PHF6 with CHD4, further confirming the

validity of our mass spectrometry results. Additionally, PHF6 co-immunoprecipitated specifically with an HDAC1 pull down, but not with IgG. While these reciprocal co-immunoprecipitations experiments confirm a nuclear interaction between PHF6 and NuRD, they were unable to define whether the interaction was primarily nucleoplasmic or nucleolar.

#### ***PHF6 and NuRD interact in the nucleoplasm***

Previous studies have suggested that NuRD is also localized to the nucleolus (Ahmad et al., 2009; Shimono et al., 2005). To investigate the localization of the PHF6-NuRD complex, we performed subcellular fractionation. We observed the majority of CHD4 to have nucleoplasmic localization, with only trace levels in the nucleolus (Figure 3-5A). Similarly, RBBP4 and HDAC1 have higher concentrations in the nucleoplasm with lower expression in the cytoplasm, and very little nucleolar expression. Therefore, it suggests that the PHF6-NuRD complex is not nucleolar but resides in the nucleoplasm. To confirm these observations, we performed immunocytochemistry to observe co-localization between the nucleolus and NuRD constituents. We observed that CHD4 and HDAC1 do not co-localize with nucleolin, a protein strictly localized to the nucleolus, whereas HDAC1 and RBBP4 showed significant co-localization with PHF6 in the nucleoplasm (Figure 3-5B).

To further elucidate the composition of PHF6 nuclear and nucleolar complexes, we performed glycerol density gradient co-sedimentation of fractionated nuclear and nucleolar lysates (Figure 3-5C). For the nuclear lysates, PHF6 was found to co-sediment with both RBBP4 and CHD4 in fractions #4-12, consistent with where the lowest

**Figure 3-5. PHF6 interacts with the NuRD complex in the nucleus, but not the nucleolus.**

(A) Subcellular fractionation analysis demonstrating that the NuRD constituents that interact with PHF6 are primarily localized in the nucleoplasm, with trace levels in the nucleolus. (B) HEK 293T cells were labeled with anti-PHF6, anti-CHD4, anti-RBBP4, and anti-HDAC1 by immunocytochemistry. PHF6 demonstrates strong nuclear and nucleolar localization (left panels), however the NuRD constituents are primarily localized to the nucleoplasm with very little (if any) nucleolar localization. These cells were also labeled with nucleolin as a marker for nucleoli (right panels). (C) Nuclear and nucleolar cell lysate fractions were separated by glycerol density gradient centrifugation. Following centrifugation, fractions were collected from the gradient and analyzed by immunoblotting with antibodies for PHF6, CHD4, and RBBP4. The numbering of the fractions corresponds to an increase in the mass of proteins or protein complexes that are found within the fraction. PHF6 was found to co-elute with the NuRD constituents in nucleoplasmic fractions, but not in nucleolar fractions. Input represents 1% of the nuclear or nucleolar lysate prior to centrifugation.

molecular weight NuRD complexes were expected. The peak of NuRD complex formation appears to occur in fractions #10-12. In larger fractions, where no PHF6 was observed, CHD4 and RBBP4 are likely co-sedimenting with higher molecular weight chromatin remodeling complexes. In contrast, CHD4 protein levels were undetectable and RBBP4 levels were low in the nucleolar lysate fractions, despite the detection of PHF6 in fractions #2-11. We conclude from these experiments that the PHF6-NuRD complex is restricted to the nucleoplasm and that PHF6 interacts with other proteins in the nucleolus and thus, likely has unique functions in these distinct nuclear compartments.

**DISCUSSION**

The NuRD complex is a multifunctional epigenetic regulator that engages in several catalytic functions, including ATP-dependent nucleosome remodeling, histone deacetylation, and H3K4 demethylation (Tong et al., 1998; Wang et al., 2009; Zhang et al., 1998). We have identified PHF6 as a novel NuRD interactor and subsequent validation of this interaction demonstrated that endogenous PHF6 co-purifies with CHD4, RBBP4, and HDAC1. While PHF6 displayed strong distribution within the nucleoplasm and the nucleolus, the NuRD complex was not abundant in the nucleoli, suggesting that PHF6 co-localizes with NuRD in the nucleoplasm. The interactions with 40S/60S ribosomal proteins, splicing factors, and other nucleolar proteins confirm a role for PHF6 in the nucleolus. Nonetheless, future studies are required to define the function of PHF6 within the nucleolus and determine how it contributes to the BFLS and T-ALL phenotypes.

***NuRD regulates developmental pathways that are affected by PHF6 mutations***

NuRD regulates critical developmental events that mediate cell proliferation and lineage commitment. Some of the developmental pathways mediated by NuRD include embryogenesis (Hendrich et al., 2001), oncogenesis (Lai and Wade, 2011), neurogenesis (Potts et al., 2011), and hematopoiesis (Yoshida et al., 2008; Zhang et al., 2012a), making PHF6-NuRD an exciting interaction to explain the mechanism responsible for the phenotype that arises when *PHF6* is mutated in BFLS and T-ALL. The specificity of NuRD towards its targets is achieved by the use of interchangeable core constituents that are mutually exclusive (e.g. MTA1/2/3, MBD2/3) (Hendrich and Bird, 1998; Yao and

Yang, 2003). These differential subunits interact uniquely with other proteins, many of which possess a zinc finger, to target NuRD to specific genomic loci.

During T-cell development, where immature CD4<sup>+</sup>CD8<sup>-</sup> double-negative thymocytes differentiate into double-positive, and then single-positive mature T-cells, NuRD actively participates in transcriptional activation and repression (Cismasiu et al., 2005; Williams et al., 2004). In some instances, the transcriptional outcome is influenced through the interaction between NuRD and a transient binding partner. For example, NuRD has been shown to promote the active transcription of the T-cell differentiation marker CD4, but the same gene is repressed by Ikaros-NuRD targeting (Naito et al., 2007). Further study of the Ikaros-NuRD interaction has demonstrated that it stably associates at transcriptionally active genes in double-positive thymocytes, and that the ablation of Ikaros leads to NuRD-mediated silencing at genes normally bound by Ikaros (Zhang et al., 2012a). Additionally, the NuRD complex becomes redistributed to other Ikaros-independent sites where it reactivates genes involved in proliferation. Similarly during neurogenesis, chromatin immunoprecipitation and target gene expression studies have demonstrated the contribution of NuRD toward the regulation of genes that contribute to neuronal development in the brain and peripheral nerve myelination, with a loss of NuRD leading to enhanced proliferation (Hung et al., 2012; Potts et al., 2011).

Like NuRD, PHF6 is expressed in both the brain/CNS (Voss et al., 2007) and double-positive thymocytes (Van Vlierberghe et al., 2010). The co-expression of PHF6 and NuRD in these tissues suggests that PHF6 could be directing NuRD to a subset of gene targets that promote the development of these tissues through lineage commitment or maturation. While this is an enticing model for consideration, we cannot attribute the

development of these tissues or the disease phenotypes solely to a PHF6-NuRD complex, as aberrant splicing or ribosome production from a lack of PHF6 in the nucleolus could just as likely account for the malignancy or neurodevelopmental defects. However, transcriptional regulation represents only one known function of the NuRD complex and thus, the contribution of PHF6 towards alternative chromatin remodeling events regulated by NuRD should not be ignored.

Another major function of NuRD involves its localization to active replication forks on pericentromeric heterochromatin during DNA replication where it facilitates DNA repair (Helbling Chadwick et al., 2009; Sims and Wade, 2011). The loss of NuRD constituents leads to defects in the maintenance of pericentromeric heterochromatin, an S phase delay, and the accumulation of DNA damage (Pegoraro et al., 2009; Sims and Wade, 2011). Interestingly, an increase in the  $\gamma$ H2AX DNA damage marker has been observed after PHF6 loss in HEK 293T cells (Van Vlierberghe et al., 2010). Moreover, both PHF6 and NuRD are targets of the ATM DNA damage checkpoint kinase (Matsuoka et al., 2007; Polo et al., 2010). Thus, the PHF6-NuRD complex could function in either transcriptional regulation or in active DNA repair. As such, future work must focus on the identification of specific genomic targets and the mechanisms that direct PHF6 to such loci.

#### ***PHF6 as a targeting protein for NuRD***

PHF6 does not contain DNA sequence recognition domains, thus its interactions with chromatin are most likely determined by its ZaP domains. While the functional role of these zinc fingers is unknown, the ZaP domain has been reported to participate in histone interactions (Darvekar et al., 2012; Saksouk et al., 2009). NuRD itself

preferentially binds H3K4me0/H3K9me3 (Mansfield et al., 2011), and many of its known binding partners (e.g. BRG1, MLL, JARID1B) interact with modified histones to target NuRD to silenced or permissive chromatin (Li et al., 2011; Nakamura et al., 2002; Shimono et al., 2003). Similarly, PHF6 may be targeting NuRD to genomic target sites with a specific histone code signature.

Another possible role for the ZaP domain is in mediating protein-protein interactions, which has been reported for TCF20 and JADE-1 (Sjottem et al., 2007; Zhou et al., 2004). For PHF6, the ZaP domains may be required for the stable association with core subunits of the NuRD complex. Interestingly, several better characterized NuRD interacting proteins (e.g. BCL11B, FOG-1, SALL1) possess an N-terminal C<sub>2</sub>HC zinc finger, similar to the zinc knuckle from the first PHF6 ZaP domain, that has been proposed to interact with the GATA-like zinc finger present in the MTA proteins (Cismasiu et al., 2005; Kowalski et al., 2002). Therefore, in addition to targeting NuRD to chromatin, future studies should consider that the PHF6 ZaP domains could also be acting as a primary interface for the interaction with NuRD.

**CONCLUSION**

In this study, we have identified a novel interaction between PHF6 and several components of the NuRD chromatin remodeling complex. The interaction with the NuRD complex represents the first PHF6 protein complex and it confirms that PHF6 is a chromatin interacting protein. We have demonstrated that while PHF6 is distributed almost equally between the nucleoplasm and the nucleolus, the PHF6-NuRD complex is specific to the nucleoplasm, suggesting that PHF6 has additional functions and interactions that pertain to the nucleolus. Further characterization of the PHF6-NuRD complex will need to be focused on the identification of target genes and the mechanisms that target PHF6 to specific genomic loci. These targets will need to be analyzed within the context of spatiotemporal developmental pathways, such as neurogenesis and hematopoiesis, in order to fully understand the contribution of PHF6 to BFLS and T-ALL.

## **ACKNOWLEDGEMENTS**

We thank Laura Trinkle-Mulcahy for reagents and technical advice with mass spectrometry analysis and nucleolar fractionation; Vahab Soleimani for advice with the Flag-IP experiments; Michael Rudnicki and Iain McKinnell for providing the pBRIT-LoxP-NTAP and pBRIT-LoxP-CTAP vectors; Jozef Gécz for providing the monoclonal PHF6 antibody; and Rashmi Kothary and Michael Huh for comments on the manuscript. This work was supported by operating grants from the Canadian Institutes of Health Research. MAMT was supported by a Natural Sciences and Engineering Research Council of Canada Postgraduate Scholarship and by an Ontario Graduate Scholarship.

## **SUPPLEMENTARY INFORMATION**

### **SUPPLEMENTARY MATERIALS AND METHODS**

#### ***Analysis of soluble and insoluble subcellular fractionation products by SDS-PAGE***

HEK 293T whole cell lysates were fractionated into cytoplasmic, nuclear, and nucleolar fractions, as described by (Chamousset et al., 2010b) and in the Materials and Methods section. Following the pelleting of insoluble protein from each fraction, the supernatants were collected as lysate fractions while the pellets were re-solubilized in 8M urea at an equivalent volume to the corresponding lysate. Additionally, the supernatant was collected at steps following the wash and subsequent pelleting of the nuclei (wash #1) and nucleoli (wash #2). These supernatants were diluted 1:5 in 5X RIPA and centrifugated at 15 000 g for 30 minutes at 4°C to pellet insoluble protein. For wash #1, the pellet was isolated from the supernatant and re-solubilized in 8 M urea at an equivalent volume to the supernatant. For wash #2, no pellet was discernible. Cytoplasmic, nucleoplasmic, nucleolar, and wash fractions were then prepared for SDS-PAGE analysis. For lysates (cytoplasmic, nucleoplasmic, nucleolar) and the wash #1 supernatant, equivalent amounts (10 µg each) were loaded onto the SDS-PAGE gel. For resuspended pellets, equivalent volumes to the corresponding loaded volumes of lysate were loaded onto the gel. For wash #2, an equivalent volume to the loaded volume of nucleolar lysate was loaded onto the gel.

#### ***Immunocytochemistry for BrdU-labeled HEK 293T cells***

Asynchronous HEK 293T cells were incubated with 30 µg/mL bromodeoxyuridine (BrdU) in DMEM with 10% FBS for 30 minutes prior to cytocentrifugation and fixation. Immunocytochemistry was performed as described in the

Materials and Methods section, with the following additional step. After permeabilization and blocking, HEK 293T cells were washed with DNase I buffer (20 mM Tris-HCl pH 7.8, 140 mM NaCl, 1 mM MgSO<sub>4</sub>) and incubated for 30 minutes at 37°C in the presence of 10 µg/mL DNase I. Following DNase I incubation, cells were washed with PBS, then incubated with primary antibody, as described. All subsequent steps remained identical to the aforementioned protocol.

**Figure 3-S1. Annotated tandem mass spectra for MAGOH (A) and NPM1 (B) single peptide assignments.** Annotated spectra were generated by Scaffold version 2.06.02 (Proteome Software) with y-ions indicated in blue and b-ions indicated in red. Corresponding amino acid sequences are indicated at the top of each panel.

**Figure 3-S2. PHF6 is present in only the soluble fractions following subcellular fractionation.** Whole cell lysates from HEK 293T were fractionated into soluble (lysate or supernatant) and insoluble (pellet) cytoplasmic, nucleoplasmic, nucleolar, and wash fractions. Soluble fractions (except wash #2) were loaded at equivalent amounts (10  $\mu$ g), while insoluble fractions were loaded at equivalent volumes to the corresponding soluble fraction. Wash #2 was loaded at an equivalent volume to the nucleolar lysate fraction. Immunoblotting was performed using antibodies to detect PHF6,  $\alpha$ -Tubulin, Lamin A/C, Fibrillarin, CHD4, RBBP4, and HDAC1. PHF6 was only detected in soluble fractions, with strong levels detected in the nucleoplasmic and nucleolar lysates. Trace levels of PHF6 were also detected in the cytoplasmic lysate. By comparison, NuRD proteins (CHD4, RBBP4, HDAC1) are most highly detected in the soluble and insoluble nucleoplasmic fractions, with lower levels present in the cytoplasmic and nucleolar soluble fractions.  $\alpha$ -Tubulin, Lamin A/C, and Fibrillarin are markers for the cytoplasm, nucleoplasm, and nucleolus respectively.

**Figure 3-S3. PHF6 is co-localized with DNA throughout the cell cycle, except during mitosis.**

(A) HEK 293T cells were briefly pulsed with BrdU to mark regions of active DNA replication prior to immunocytochemistry using antibodies to detect PHF6 and BrdU. PHF6 is expressed in the nucleoplasm and nucleoli during interphase and throughout S-phase. (B) HEK 293T cells were co-labeled with PHF6 and  $\alpha$ -Tubulin antibodies by immunocytochemistry.  $\alpha$ -Tubulin marks the mitotic spindle, and mitotic chromosomes are observed by DAPI staining. While PHF6 does not co-localize with mitotic chromosomes during metaphase and anaphase, it does so during telophase.

**Figure 3-S4. Expression levels of PHF6-TAP in clonally derived cell lines.** HEK 293T cells stably expressing PHF6-NTAP (A) or PHF6-CTAP (B) were clonally derived and whole cell lysates were analyzed by immunoblotting with antibodies for PHF6 and Flag. Whole cell lysates from pooled PHF6-NTAP and PHF6-CTAP cell lines were simultaneously analyzed by immunoblotting to provide a comparative analysis of expression levels.

**Table 3-S1. Summary of antibodies used for Western blotting (W), immunocytochemistry (ICC), and immunoprecipitation (IP).**

Antibody	Source	Application
<i>Primary antibodies</i>		
PHF6 (rabbit) <sup>a</sup>	Bethyl Labs (A301-450A)	ICC (1:500) (not shown)

## **CHAPTER 4**

**RNA tethers PHF6 to the nucleolus to mediate  
rDNA transcript levels**

## **Purpose**

To observe how PHF6 is recruited to the nucleolus, identify the nucleolar sub-compartments to which it is localized, and determine the function of PHF6 with respect to rRNA synthesis.

## **Submission Information**

Manuscript submitted to the *Journal of Medical Genetics* on 10 November 2014.

## **Contribution of Co-Authors**

Matthew A.M. Todd performed all of the experimental work and analysis, with the exception of the Pyronin Y staining shown in Figure 4-S2A, which was carried out by Michael S. Huh. The manuscript was written by Matthew A.M. Todd and edited by David J. Picketts.

**ABSTRACT**

**Background:** Ribosomal RNA synthesis occurs in the nucleolus and is a tightly regulated process that is targeted in some developmental diseases and hyperactivated in multiple cancers. Subcellular localization and immunoprecipitation coupled mass spectrometry demonstrated that a proportion of plant homeodomain (PHD) finger protein 6 (PHF6) protein is localized within the nucleolus and interacts with proteins involved in ribosomal processing. While *PHF6* mutations cause Börjeson-Forssman-Lehmann syndrome (BFLS, MIM#301900) and occur in cases of T-cell acute lymphoblastic (MIM#613065) and acute myeloid leukemia (MIM#601626), very little is known about its cellular function including its nucleolar role. **Methods:** HEK 293T cells were treated with RNase A, DNase I, actinomycin D, or 5,6-dichloro- $\beta$ -D-ribofuranosylbenzimidazole, followed by immunocytochemistry to determine PHF6 sub-nucleolar localization. Stable cell lines that overexpress or knockdown PHF6 were used for ChIP-qPCR and qRT-PCR studies to determine the effect on rDNA expression. **Results:** We observed the RNA-dependent localization of PHF6 to the subnucleolar fibrillar center and dense fibrillar component, at whose interface rRNA transcription occurs. Subsequent analysis by ChIP-qPCR revealed strong enrichment of PHF6 across the entire rDNA coding sequence, but not in the intergenic spacer (IGS) region. When rRNA levels were quantified in a PHF6 gain-of-function model, we observed an overall decrease of 47S pre-rRNA and 28S rRNA. These losses were accompanied by a modest increase in repressive promoter-associated RNA (pRNA) and a significant increase in the levels of IGS<sub>36</sub>RNA and IGS<sub>39</sub>RNA. **Conclusions:** Collectively, our results demonstrate a role for PHF6 in carefully mediating the overall levels of ribosome biogenesis within a cell.

## INTRODUCTION

Mutations in the X-linked gene coding for PHF6 are associated with both germline and acquired human disease. *PHF6* mutations are the only known cause of BFLS (MIM#301900), a congenital disorder characterized by intellectual disability, truncal obesity, gynaecomastia, hypogonadism, as well as facial and digit abnormalities (Gecz et al., 2006; Lower et al., 2002). Somatic *PHF6* mutations also frequently occur in cases of T-ALL (~20-40%), AML (~3%), and CML (~2%) (Grossmann et al., 2013; Huether et al., 2014; Huh et al., 2013; Li et al., 2013; Patel et al., 2012; Van Vlierberghe et al., 2010; Van Vlierberghe et al., 2011; Yoo et al., 2012). In comparison, BFLS mutations are largely missense mutations whereas leukemic *PHF6* mutations overwhelmingly consist of truncations, frameshifts, and deletions, suggesting that severe loss-of-function mutations may favour oncogenesis (Todd and Picketts, 2012; Van Vlierberghe et al., 2010). In this regard, few BFLS patients develop leukemia although we have reported bone marrow cancers, including T-ALL, in two BFLS patients (Carter et al., 2009; Chao et al., 2010). Nonetheless, whether PHF6 loss is a primary or secondary event to the onset of leukemia remains to be determined.

Structurally, the PHF6 protein consists of two ZaP domains (Zinc knuckle, atypical PHD) as well as both nuclear and nucleolar localization sequences (Todd and Picketts, 2012). While the specific function of PHF6 remains unclear, we have previously shown that PHF6 co-purifies with multiple constituents (CHD4, RBBP4, HDAC1) of the nucleosome remodeling and deacetylation (NuRD) complex, an important developmental regulator of gene expression during embryogenesis and lineage commitment, with particularly well characterized responsibilities during lymphogenesis (Todd and Picketts,

2012; Zhang et al., 2012a). While NuRD is known to regulate transcription in both the nucleoplasm and nucleolus (Xie et al., 2012), we found that the PHF6-NuRD interaction was restricted to the nucleoplasm. These findings have since been validated by Liu et al., who confirmed a direct interaction between PHF6 and RBBP4 (Liu et al., 2014). More recently, an association between PHF6 and the PAF1 transcriptional elongation complex was reported (Zhang et al., 2013). The PHF6-PAF1 complex was essential for allowing the complete transcription of targets such as *NGC/CSPG5*, thus ensuring proper neuronal migration in murine cerebral cortices. Other studies have shown that the second Zap domain of PHF6 interacts with double-stranded DNA, indicating that PHF6 may serve as a targeting molecule for these transcriptional regulatory complexes (Liu et al., 2014).

In addition, a significant proportion of the PHF6 protein is localized within the nucleolus, where it interacts with several nucleolar proteins (Todd and Picketts, 2012). Nucleoli are subnuclear compartments that form around nucleolar organizer regions (NORs) at rDNA tandem repeats. Each 43 kb rDNA gene repeat (GenBank, U13369) consists of a coding sequence for the 13 kb polycistronic 47S pre-rRNA transcript followed by a 30 kb intergenic spacer (IGS) region. Nucleoli primarily serve as centers for ribosome biogenesis, during which 47S pre-rRNA is transcribed, processed into 18S, 5.8S, and 28S rRNA, and incorporated into 60S and 40S ribosomes (Tschochner and Hurt, 2003). Ribosomal output is directly proportional to nucleolar size, and large nucleoli have been correlated with poor cancer prognoses (Derenzini et al., 2009). Furthermore, nucleolar dysregulation is linked to several human developmental diseases, including those with intellectual disability, and neurological disorders such as Alzheimer's and Parkinson's disease (Hannan et al., 2013; Hetman and Pietrzak, 2012).

Structurally, the nucleolus consists of three compartments (Figure 4-1A): the fibrillar center (FC), where rDNA is located, the dense fibrillar center (DFC), where early rRNA processing occurs, and the granular component (GC), where later rRNA processing occurs, with the actual transcription of pre-rRNA occurring at the interface between the FC and the DFC (Boisvert et al., 2007; Denissov et al., 2011). In this regard, both PHF6-containing complexes NuRD and PAF1 are known to mediate RNA Pol I-dependent rRNA transcription in addition to their RNA Pol II targets, suggesting that PHF6 may regulate rDNA transcription (Xie et al., 2012; Zhang et al., 2010b). Moreover, PHF6 can be recruited to the rDNA promoter by upstream binding factor (UBF), a major transcriptional activator during rRNA synthesis (Wang et al., 2013). In contrast, proteomic studies from our lab identified interactions between PHF6 and ribosomal proteins involved in rRNA processing, indicating that further studies are required to fully dissect the specific nucleolar responsibilities with which PHF6 is tasked.

The objective of this study was to utilize subnucleolar fractionation to further elucidate the role of PHF6 in regulating rDNA expression. We observed that nucleolar PHF6 is localized within both the FC and DFC compartments, where it binds to transcribed regions of rDNA and suppresses rRNA transcription. We also report the novel findings that PHF6 is recruited to the nucleolus by an RNA tethering mechanism and that the suppression of rRNA was coincidental with elevated levels of the non-coding IGS<sub>36</sub>RNA, IGS<sub>39</sub>RNA, and unprocessed promoter RNA (pre-pRNA) transcripts. Overall, our findings confirm a specific role for PHF6 in modulating the expression of multiple transcripts from rDNA repeats.

**Figure 4-1. A subset of nuclear PHF6 localizes to the nucleolus.**

(A) The nucleolus consists of three subnucleolar compartments: the fibrillar centre (FC), the dense fibrillar component (DFC), and the granular component (GC). The rDNA is located within the FC and 47S pre-rRNA is transcribed at the FC/DFC interface. rRNA processing occurs within the DFC and GC. (B) Confocal imaging of HeLa cells immunofluorescently stained with antibodies to PHF6 (green) and subnucleolar markers (red) representing the FC (UBF), DFC (FBRL), or GC (NCL). PHF6 partially co-localizes with markers for each subnucleolar compartment in intact nucleoli from untreated cells. Representative cell images are shown.

## **MATERIALS AND METHODS**

### ***Cell culture and chemical treatments***

HeLa and HEK 293T cells were cultured at 37° C in DMEM supplemented with 10% FBS and 1% penicillin-streptomycin (Life Technologies). For chemical treatment assays, cultures were supplemented with either, 0.5 µg/mL ActD (Sigma), 25 µg/mL and 5,6-dichloro-β-D-ribofuranosylbenzimidazole (DRB, Sigma), or 5 µg/mL α-amanitin (Sigma) for two hours, then immediately harvested for immunocytochemistry. As a control, some DRB treated cells were cultured for an additional 2 hours in DRB-free media prior to fixation. The generation of HEK 293T stable cell lines expressing either the pBRIT-LoxP-PHF6-NTAP or pBRIT-LoxP-PHF6-CTAP plasmids was previously described (Todd and Picketts, 2012), and these cells were cultured in the DMEM media additionally supplemented with 1.5 µg/µL puromycin (Sigma).

### ***Immunocytochemistry***

Chemically treated cells were trypsinized and washed with PBS on ice prior to cytocentrifugation using the Cytospin system (Thermo Shandon). Approximately 15 000 cells were applied per slide by centrifugation at 800 g for 5 minutes. Cells were fixed for 10 minutes on ice in 4% paraformaldehyde in CSK buffer (10 mM PIPES pH 6.8, 10 mM NaCl, 300 mM sucrose, 3 mM MgCl<sub>2</sub>, 2 mM EDTA), then washed with PBS before permeabilizing for 10 minutes with 0.5% Triton X in PBS at room temperature. Cells were blocked for 1 hour at room temperature in PBS with 20% horse serum and 0.5% FBS. PHF6 (Sigma, HPA001023; 1:1000), UBF (Santa Cruz, sc-13125; 1:1000), fibrillarin (Abcam, ab4566; 1:1000), coilin (BD Biosciences, 612074; 1:1000), and nucleolin (Millipore, 05-565; 1:250) primary antibodies were diluted in PBS and

incubated with the fixed cells overnight at 4°C in a humidifying chamber. Alexa Fluor 488 (A21202) and 594 (A21207) secondary antibodies (Life Technologies; 1:4000) were incubated for 40 minutes at room temperature, prior to washing and mounting slides (DAKO) for microscopy.

### ***Nuclease treatments***

Nuclease treatments were adapted from the previously described method of (Chamousset et al., 2010a). Briefly, slides containing HEK 293T (~15 000) cells were rinsed once with PBS and once with ASE buffer (20 mM Tris pH 7.5, 5 mM MgCl<sub>2</sub>, 0.5 mM EGTA), then permeabilized (5 min, room temperature) in ASE buffer containing 0.1% Triton X-100. Cells were then incubated (20 min, room temperature) with 10 µg/mL DNase I or 100 µg/mL RNase A in ASE buffer. Untreated control incubations were performed in nuclease-free ASE buffer. Cells were prepared for immunocytochemistry as described above. DAPI (100 ng/mL, 3 min, room temperature) staining was used to visualize DNA, while RNA was visualized by incubating cells with 10 µM Pyronin Y for 10 minutes (after DAPI).

### ***Image acquisition and processing***

All cell images were captured with a Plan-Apochromat 63x/1.40 Oil DIC M27 objective on a Zeiss LSM 510 laser scanning confocal microscope, equipped with UV (405 nm), argon (488 nm), and helium/neon (546 nm) lasers. Images were initially acquired with Zeiss ZEN 2009 software using a zoom factor of 1.5, then exported to Zeiss LSM Image Browser v.4.2.0.121 software for contrast processing and cropping.

**Chromatin immunoprecipitation**

Chromatin immunoprecipitation (ChIP) was performed using the EZ-ChIP protocol (Millipore, #17-371). Briefly, adherent HEK 293T cells were grown on 10 cm tissue culture plates (80-90% confluency), crosslinked with 1% formaldehyde for 10 minutes at room temperature, washed with ice cold PBS, and scraped. Harvested cells were resuspended in SDS lysis buffer (50 mM Tris-HCl pH 7.8, 10 mM EDTA, 1% SDS; 1 mL buffer for every  $10^7$  cells), then sonicated (5 x 10 second pulses, 30% amplitude). The average chromatin fragment size was determined to be about 400-500 bp as confirmed by agarose gel electrophoresis. Sonicated lysates were centrifugated at 10 000 g for 10 minutes to pellet insoluble material and divided into 100  $\mu$ L aliquots ( $\sim 10^6$  cells), then 900  $\mu$ L of ChIP dilution buffer was added to each aliquot (16.7 mM Tris-HCl pH 7.8, 167 mM NaCl, 1.2 mM EDTA, 1.1% Triton X-100, 0.01% SDS). Diluted lysates were pre-cleared, then 10  $\mu$ L of the sample was removed as 1% input. The remaining aliquot was then incubated with 1  $\mu$ g of mouse/rabbit IgG (Jackson) or one of the PHF6, CTCF (Millipore, 07-729), UBF, or histone H3 (Abcam, ab1791) primary antibodies overnight at 4° C with rotation. Antibody-protein complexes were then captured by adding 60  $\mu$ L (25% slurry) of pre-blocked Protein G-agarose (Santa Cruz, for mouse)/Protein A-sepharose (GE Healthcare, for rabbit), and beads were subsequently washed once with low salt wash buffer (20 mM Tris-HCl pH 7.8, 150 mM NaCl, 2 mM EDTA, 1% Triton X-100, 0.1% SDS), once with high salt wash buffer (20 mM Tris-HCl pH 7.8, 500 mM NaCl, 2 mM EDTA, 1% Triton X-100, 0.1% SDS), once with LiCl wash buffer (10 mM Tris-HCl pH 7.8, 1 mM EDTA, 1% deoxycholate, 1% Nonidet P-40, 250 mM LiCl), and twice in Tris-EDTA buffer. An equivalent volume of elution

buffer (1% SDS, 100 mM NaHCO<sub>3</sub>) was then added to the washed beads and 1% input aliquots, followed by an overnight at 65° C in the presence of 200 mM NaCl to reverse the crosslinks. Residual RNA and protein were eliminated by digesting with 10 µg of RNase A and 10 µg of proteinase K respectively. Final DNA products were purified by phenol-chloroform extraction and resuspended in Tris-EDTA buffer in preparation for subsequent qPCR analysis.

### ***RNA extraction and quantitative real-time PCR***

RNA extractions were performed from 10<sup>6</sup> cells (per experiment) using an RNeasy Mini Kit (Qiagen). Total RNA (1 µg) was used for reverse transcription (RT) with random primers and SuperScript III enzyme (Life Technologies) to generate cDNA. ChIP-DNA or RT samples were prepared for qPCR using SYBR Green Advantage qPCR premix (Clontech) and reactions performed on an Mx3000P system (Stratagene). All primer sets are listed in Table 4-S1. For ChIP-qPCR reactions, rDNA fold changes between ChIP products and 1% input were calculated using the following equation: fold change =  $2^{-(\text{input } C_t - \text{ChIP } C_t)}$ . For qRT-PCR reactions, fold changes were calculated with the  $\Delta\Delta C_t$  method using GAPDH as an internal control.

### ***Statistics***

Statistical analyses were performed in Microsoft Excel. Two-tailed t tests, 95% confidence intervals, and 99% confidence intervals were used to determine significance.

## RESULTS

### *PHF6 localizes to the nucleolar FC and DFC*

We previously performed cellular fractionation studies indicating that PHF6 is present within the nucleoplasm and nucleolus (Todd and Picketts, 2012). To better understand the nucleolar role of PHF6 and its subnucleolar localization, we performed immunocytochemistry to determine if PHF6 co-localizes with any markers for the nucleolar subcompartments: UBF (FC marker), fibrillarin (FBRL, DFC marker), or nucleolin (NCL) (GC marker). As shown in Figure 4-1B, these initial studies showed some overlap of PHF6 localization with each marker, yet they were inconclusive in distinguishing a specific compartment within which PHF6 resides. As such, we proceeded to use chemical-based treatments as a more definitive means of achieving separation between the nucleolar subcompartments.

To better delineate how PHF6 localizes within the nucleolus, HEK 293T cells were treated with actinomycin D (ActD) and DRB to induce nucleolar reorganization, as previously described (Chamousset et al., 2010a). Briefly, ActD induces nucleolar disassembly by inhibiting RNA Pol I, thereby arresting pre-rRNA transcription, while DRB inhibits casein kinase 2 to uncouple the rRNA processing machinery from RNA Pol I-mediated transcription. Unlike the ActD treatment, the effects of DRB are reversible upon its removal, and RNA Pol I will continue to transcribe pre-rRNA upon nucleolar disassembly (Scheer et al., 1984). Studies of nucleolar disassembly in response to chemical treatments and during mitosis have previously demonstrated that proteins found in particular nucleolar compartments remain associated with one another during nucleolar reorganization, thus the co-localization of PHF6 with particular markers before and after

**Figure 4-2. PHF6 co-localizes with the nucleolar FC and partially co-localizes with the DFC.**

(A) Nucleoli can be partially or completely disassembled in response to chemical treatment. 5,6-dichloro-1-beta-D-ribofuranosylbenzimidazole (DRB) causes the uncoupling of rRNA processing from rDNA transcription, while actinomycin D (ActD) inhibits RNA pol I at low concentrations. During nucleolar reorganization, proteins that are found in the same nucleolar compartments commonly remain associated in the same nascent foci. HEK 293T cells were treated with either 25  $\mu\text{g}/\text{mL}$  DRB or 0.5  $\mu\text{g}/\text{mL}$  ActD for 2 hours. Cells were then fixed and labeled with antibodies to PHF6 (green) and either (B) UBF, (C) FBRL, or (D) NCL (red), then visualized by confocal microscopy. PHF6 strongly co-localizes with UBF in both the DRB and ActD treatments, and also partially co-localizes with FBRL foci. Representative cell images are shown. Additional controls for these chemical treatments are shown in Figure 4-S1.

treatment would imply its association with that particular nucleolar compartment (Figure 4-2A) (Dundr et al., 2000; Scheer et al., 1993; Weisenberger and Scheer, 1995).

HEK 293T cells were treated with 0.5  $\mu\text{g}/\text{mL}$  ActD or 25  $\mu\text{g}/\text{mL}$  DRB for 2 hours prior to immunocytochemistry and confocal microscopy, with untreated cells serving as a negative control (Figure 4-2B,C,D) (Scheer et al., 1984; Zandomeni et al., 1986). In both the ActD and DRB treatments, PHF6 was found to co-localize with UBF (Figure 4-2B) and partially co-localize with FBRL (Figure 4-2C), but did not co-localize with NCL (Figure 4-2D). Because ActD (at higher concentrations) and DRB are known to inhibit RNA Pol II, we also treated HEK 293T cells with  $\alpha$ -amanitin (5  $\mu\text{g}/\text{mL}$ , 2 hours), which specifically inhibits RNA Pol II but not RNA Pol I (Lindell et al., 1970). As shown in Figure 4-S1A, the  $\alpha$ -amanitin treatment did not induce nucleolar reorganization. Additionally, HEK 293T cells that were treated with 25  $\mu\text{g}/\text{mL}$  DRB for 2 hours were also grown in untreated media (without DRB) for a further 2 hours to assess the reversibility of the DRB-induced nucleolar disassembly. Indeed, the DRB-induced PHF6 reorganization proved to be reversible (Figure 4-S1A).

Cajal bodies exist as known sites for snRNP/snoRNP biogenesis, and are recruited to nucleoli in response to DRB exposure as well as other instances of nucleolar stress (Boulon et al., 2010). To rule out the possibility that PHF6 was associating with Cajal bodies, we also co-labeled ActD and DRB treated cells with PHF6 and COILIN, a marker for Cajal bodies. However, for each treatment, we did not observe any co-localization between PHF6 and COILIN (Figure 4-S1B). Thus from these experiments, we conclude that PHF6 is most likely localized to the interface between the FC and the DFC, where rDNA is transcribed.

***PHF6 localization to the nucleolus is RNA-dependent***

The FC/DFC interface is the site where 47S pre-rRNA is transcribed from rDNA, and harbours proteins with the ability to interact with DNA and/or RNA. Since PHF6 was reported to bind to dsDNA and be recruited to the rRNA promoter, we expected the nucleolar recruitment of PHF6 to be DNA-dependent (Liu et al., 2014; Wang et al., 2013). To test this hypothesis, HEK 293T cells were permeabilized and digested with 10 µg/mL of DNase I or 100 µg/mL of RNase A prior to fixation and immunocytochemistry using confocal microscopy for PHF6 and UBF (DNA-dependent marker) or nucleolin (RNA-dependent marker) (Figure 4-3A,B). UBF binds coding rDNA as a transcriptional activator. The DNase treatment resulted in the loss of UBF binding in the nucleolus, but RNase treatment had no effect (Figure 4-3A). DNA loss is apparent with DNase, as demonstrated by reduced DAPI staining (Figure 4-3A). To our surprise, nucleolar PHF6 remained in the nucleolus after the DNase treatment (Figure 4-3A,B), but was lost following RNase treatment, suggesting that PHF6 is mainly associated with the nucleolus through an RNA-based mechanism. As expected, we observed nucleolin localization to be dependent on RNA, but not DNA (Figure 4-3B). As a control, treated cells were stained with Pyronin Y to label RNA, demonstrating rRNA loss in the RNase treatment, but not with DNase (Figure 4-S2A). Fibrillarin was also found to be significantly depleted from nucleoli following RNase treatment, but not with DNase (Figure 4-S2B). Taken together, we conclude that PHF6 requires an association with RNA in order to be localized within the nucleolus. Since fibrillarin associates with both rDNA and rRNA in the nucleolus, but was only lost after the RNase treatment in our hands, we cannot exclude the possibility that PHF6 interacts with both DNA and RNA (Ochs et al., 1985).

**Figure 4-3. The nucleolar localization of PHF6 is RNA-dependent.**

(A, B) HEK 293T cells were treated with either DNase I (10  $\mu\text{g}/\text{mL}$ ) or RNase A (100  $\mu\text{g}/\text{mL}$ ) then immunofluorescently stained with antibodies to PHF6 (green) and UBF (A; red), or NCL (B; red). DAPI counterstain was used to visualize DNA within the nuclei. Treatment with RNase A results in the near loss of PHF6 from the nucleolus. Conversely, nucleolar PHF6 expression is not affected following treatment with DNase I. The efficacy of the DNase I treatment is confirmed by accompanying reduction in DAPI intensity. Representative cell images are shown. PHF6 co-localization controls with Pyronin Y (to visualize RNA) and FBRL are shown in Figure 4-S2.

***PHF6 binds to the rDNA transcribed regions***

The localization of PHF6 to the FC and DFC strongly implicates a role for PHF6 in the regulation of rRNA transcription, which occurs at the boundary separating these two nucleolar compartments. As such, we sought to determine if (i) PHF6 binds rDNA itself, and (ii) if PHF6 binds to the pre-rRNA coding sequence or to IGS sequences, by performing chromatin immunoprecipitation followed by quantitative PCR (ChIP-qPCR) using previously described primer pairs along the entire length of the 43 kb rDNA gene (Figure 4-4A) (Zhu et al., 2010). It has long been known that the IGS contains multiple RNA Pol I responsive promoters, which can be correlated with the recent identification of multiple non-coding IGS transcripts (Cassidy et al., 1987; Jacob et al., 2012; Kuhn and Grummt, 1987; Moss and Birnstiel, 1979; Moss et al., 1980). In one such instance, an IGS transcript originates from a promoter ~2 kb upstream from the rRNA TSS and is processed into 150-250 nt RNA molecules which are complementary to the rDNA promoter itself (Mayer et al., 2006). These so-called promoter-associated RNAs (pRNA) can subsequently silence rRNA transcription through the recruitment of the nucleolar remodeling complex (NoRC) and DNMT3B (Mayer et al., 2006; Schmitz et al., 2010). In another example, non-coding IGS<sub>16</sub>RNA/IGS<sub>22</sub>RNA, and IGS<sub>28</sub>RNA (each numbered with respect to its downstream position from the TSS in kb) become induced in response to environmental stress (e.g. heat shock, acidosis), binding HSP70 and VHL respectively, sequestering these proteins in a nucleolar detention center whose formation leads to an arrest in rRNA synthesis (Audas et al., 2012; Jacob et al., 2013). The identification of these transcripts may indeed be the tip of the iceberg as multiple non-coding RNAs appear to be expressed across the entire IGS (Audas et al., 2012).

**Figure 4-4. PHF6 binds to the transcribed regions of rDNA repeats to mediate the expression of rDNA coding and non-coding transcripts.**

(A) Schematic diagram of the rDNA gene repeat, showing the intergenic spacer (IGS) region (red), the rDNA promoter (yellow), and the rRNA coding region (green). Primer pairs were designed to amplify IGS sequences (A, -20188/-20077; B, -6942/-6839; C, -3712/-3610), the promoter sequence (D, -1017/-924), and the coding sequences (E, -47/+32; F, +307/+445; G, +8204/+8300; H, +12855/+12970) for ChIP-qPCR (panels B, C) or qRT-PCR (panels D, E) experiments. The locations of sequences corresponding to non-coding IGS and unprocessed pRNA (pre-pRNA) transcripts are indicated in blue. (B) PHF6 enrichment throughout the rDNA repeat was determined by ChIP-qPCR (n=5) analysis performed from approximately  $10^6$  HEK 293T cells (per experiment). CTCF (n=3) and UBF (n=4) ChIP-qPCR products were quantitated as controls for binding to the coding rDNA promoter and transcribed regions, respectively. For each antibody, the individual bars on the graph represent the binding (relative to 1% input) for individual primer sets in sequential order: IGS (primer sets A-C, red), promoter (primer set D, yellow), and transcribed (primer sets E-H, green). (C) Histone H3 (n=3) ChIP-qPCR was performed as an additional positive control. (D, E) qRT-PCR analysis (n=5) of RNA isolated from HEK 293T cell lines expressing empty vector or PHF6 overexpression cell lines (PHF6-NTAP, PHF6-CTAP). Given the large fold changes observed with primer sets B and C, these samples were plotted separately (panel E). All Ct values were normalized to GAPDH amplification and fold changes are calculated relative to the empty vector dCt value for all treatments. Bars represent standard error (\*p<0.05, \*\*p<0.01, two-tailed student's t-test). For the quantification of rRNA under conditions of PHF6 knockdown, see Figure 4-S5B.

As shown in Figure 4-4B, ChIP-qPCR for endogenous PHF6 demonstrated significant enrichment of PHF6 at the transcriptional start site (TSS) and in the rDNA coding sequence (-47/+32; +307/+445; +8204/8300; +12855/12970 primer sets), with less binding at the promoter (-1017/-924 primer set), and little to no binding in the IGS (-20188/-20077; -6942/-6839; -3712/-3610 primer sets) in comparison to IgG ChIP-qPCR. To confirm the specificity of the purified DNA fragments, we also performed ChIP-qPCR for CTCF, which preferentially marks the boundaries between active and inactive chromatin, and UBF (Figure 4-4B) (Barski et al., 2007). Consistent with previous reports, CTCF only bound the rRNA promoter sequence, while UBF was bound to the entire rDNA coding sequence, and most highly enriched at the 5' end (van de Nobelen et al., 2010). Histone H3 ChIP-qPCR was performed as an additional positive control, demonstrating strong enrichment throughout the rDNA repeat, including the IGS sequences (Figure 4-4C). Knowing now that PHF6 preferentially binds actively transcribed rDNA coding region, we next sought to determine how this bound PHF6 may contribute to the synthesis of rRNA.

#### ***PHF6 overexpression represses rRNA and activates non-coding IGS transcripts***

PHF6 has previously been linked to RNA Pol II-mediated transcription through its nucleoplasmic associations with NuRD and PAF1. Knowing that PHF6 binds the rDNA coding sequence, we next asked whether this binding serves to enhance or repress rRNA expression by quantitating rRNA levels in a PHF6 gain-of-function model. For our model, we utilized stable cell lines overexpressing N- or C-terminally Flag-tagged PHF6 (PHF6-NTAP, PHF6-CTAP), which we previously employed to co-purify PHF6-NuRD (Todd and Picketts, 2012). As an additional control, PHF6 shRNA knockdown was stably

achieved using pGIPZ lentivirus (Open Biosystems) in three cell lines, each expressing a different shRNA sequence. PHF6 overexpression or knockdown in these cell lines was confirmed at both the mRNA and protein levels (Figure 4-S3A,B,C). Previously, the knockdown of PHF6 in HeLa cells was reported to cause a reduction in cell proliferation and with an associated cell cycle arrest at G<sub>2</sub>/M (Wang et al., 2013). However, we did not observe any noticeable changes in the proliferation rates of our PHF6 shRNA cell lines after seeding our cell lines at a low confluency and monitoring cell proliferation over five days (Figure 4-S3D). Furthermore, when PHF6 shRNA cell lines were given a 1 hour pulse of 30  $\mu$ M BrdU, then quantitated for BrdU and propidium iodide over a 24 hour time course, no obvious cell cycle delays were apparent (Figure 4-S4). Conversely, we observed reduced rates of cell proliferation in our overexpression model after five days (Figure 4-S3E), which seems consistent with the perceived role of PHF6 as a tumour suppressor.

To quantitate rRNA, overexpression and knockdown cell lines were seeded at a low confluency and total RNA was isolated after two days for qRT-PCR analysis using the primer sets indicated in Figure 4-4A, which account for the following potential transcripts: 28S rRNA (+8204/8300; +12855/12970), 47S pre-rRNA (+307/+445), unprocessed pre-pRNA (-1017/-924), IGS<sub>23</sub>RNA (-20188/-20077), IGS<sub>36</sub>RNA (-6942/-6839), and IGS<sub>39</sub>RNA (-3712/-3610). When normalized to pre-pRNA, levels of the 47S pre-rRNA transcripts were about 100-fold higher, consistent with previous observations (Mayer et al., 2006), while levels of 28S rRNA are approximately 10<sup>4</sup>-10<sup>6</sup> times more elevated than pre-pRNA (Figure 4-S5A). When rRNA levels were quantitated in the PHF6 overexpression cell lines, statistically significant decreases in the relative amounts

of 47S pre-rRNA and 28S rRNA were observed for the +307/+445, +8204/8300, and +12855/12970 primer sets (Figure 4-4D), indicative of a reduction in the transcription of rRNA. There was also a reduction in IGS<sub>23</sub>RNA transcript levels for which no function has yet been attributed. Unexpectedly, we also observed elevated transcript levels for pre-pRNA (Figure 4-4D) as well as the IGS<sub>36</sub>RNA and IGS<sub>39</sub>RNA transcripts (Figure 4-4E). Indeed, levels of the IGS<sub>39</sub>RNA transcript were only 2-5X lower than those of the 47S pre-rRNA in our overexpression cell lines (Figure 4-S5A). Thus we observe that the outcome of enhanced PHF6 binding to the rDNA coding sequence is a reduction in rRNA synthesis and an activation of pre-pRNA and IGS RNA approximately 3.5-7 kb upstream of the TSS. In contrast to our overexpression model, no consistent or significant changes were observed amongst rDNA transcript levels following PHF6 knockdown (Figure 4-S5B).

## DISCUSSION

Mutations in genes encoding chromatin remodeling proteins are well appreciated as a cause of developmental disorders and many of these genes are now being increasingly identified as altered in various cancers. In this regard, PHF6 mutations are the cause of BFLS and have been identified in T-ALL, AML, and CML. Despite the dual disease role for PHF6 very little is known about its function and how mutations can contribute to disease pathology. Previously, we demonstrated that PHF6 is localized both in the nucleoplasm and in the nucleolus suggesting that it may have distinct subnuclear functions. We now report that nucleolar PHF6 localizes to the FC and DFC of the nucleolus, at whose interface rRNA transcription and early rRNA splicing occurs. Interestingly, PHF6 requires RNA to localize to the nucleolus, but once properly localized, it binds to rDNA coding sequences. Upon the overexpression of PHF6, we observed a decrease in overall 47S pre-rRNA and 28S rRNA levels, which coincided with enhanced expression of repressive pre-pRNA and non-coding IGS RNA in a region approximately 3.5-7 kb upstream of the rDNA TSS, suggesting that PHF6 mediates overall levels of ribosome biogenesis.

RNA Pol I-mediated elongation of pre-rRNA is a key regulatory step during ribosome biogenesis and is coupled with the downstream processing of rRNA (Schneider, 2012; Schneider et al., 2007). Previous work has shown that PHF6 interacts with the PAF1 transcriptional elongation complex to mediate RNA Pol II transcription (Zhang et al., 2013). Other studies have also shown that the PAF1 complex activates RNA Pol I-mediated elongation during rRNA synthesis (Zhang et al., 2010b). Taken together, it suggests that PHF6 may be interacting with PAF1 to mediate transcriptional elongation

of the rDNA gene. Consistent with this idea, our CHIP-qPCR results demonstrated strong enrichment of PHF6 protein at the TSS and across the entire rDNA gene body, which differs from one other study that found PHF6 only at the promoter region (Wang et al., 2013). Nonetheless, this study suggested that PHF6 was a suppressor of rRNA synthesis. Indeed, we demonstrated that overexpression of PHF6 reduced 47S pre-rRNA and 28S rRNA levels further suggesting that PHF6 may have a repressive effect on RNA Pol I-mediated elongation and a consequent uncoupling with rRNA processing.

When PHF6 is overexpressed, we also observed increased expression levels of pre-pRNA, IGS<sub>36</sub>RNA, and IGS<sub>39</sub>RNA transcripts. It has been well documented that pRNA contributes to the epigenetic silencing of rRNA through direct interactions with NoRC and DNMT3B, which methylate histones and DNA respectively (Mayer et al., 2006; Schmitz et al., 2010). While the roles of IGS<sub>36</sub>RNA and IGS<sub>39</sub>RNA transcripts are not as well characterized, they are upregulated under conditions of transcriptional stress (Audas et al., 2012). Since PHF6 does not bind to these regions, one possible explanation is that RNA Pol I transcription is redirected to these regions to further promote rDNA gene silencing when rRNA elongation is repressed.

Finally, we observed that PHF6 localization to the nucleolus was an RNA-dependent process despite its binding to the rDNA locus. Interestingly, this finding is similar to fibrillarin, which also localizes to the FC/DFC boundary and associates with rRNA and rDNA (Ochs et al., 1985). Since rRNA transcription and early processing events occur at the FC/DFC boundary, it suggests that the ability of PHF6 to interact with both RNA and DNA may be critical for ribosome biogenesis regulation. PHF6 contains two ZaP nucleic acid interaction domains, and the second of these domains is known to

bind dsDNA (Liu et al., 2012; Liu et al., 2014). Interestingly, point mutations within the first ZaP domain of PHF6 were shown to be essential for nucleolar localization, although it was proposed to be an interaction surface for UBF and thus, indirect recruitment (Wang et al., 2013). Given that both ZaP domains of PHF6 share strong homology, we propose that PHF6 may interact with nascent pre-rRNA through its first ZaP domain, while binding to rDNA through its second ZaP domain. In this way, PHF6 may potentially serve as a scaffolding bridge between the processes of elongation and early rRNA processing within the FC and DFC.

Abnormal nucleoli are a hallmark of several developmental and acquired human diseases, including intellectual disability and cancer, respectively. Dysfunctional ribosome biogenesis results from mutations that target key aspects in the regulation of rDNA, including epigenetic activation/silencing, the RNA Pol I transcriptional machinery, or the post-transcriptional processing of pre-ribosomes and maturing rRNA transcripts (Hannan et al., 2013). We have provided evidence that PHF6 is localized to the FC/DFC boundary within the nucleolus where it is likely involved in the regulation of rRNA transcriptional elongation and early rRNA processing events. Future efforts should be directed at defining its specific role in ribosome biogenesis and delineating how PHF6 mutations promote disease pathogenesis.

## **ACKNOWLEDGEMENTS**

Laura Trinkle-Mulcahy, Robin Parks, Keqin Yan, Jeff Hamill, Matias Alvarez-Saavedra, Danton Ivanochko, and Lemuel Racacho provided reagents and/or technical advice. Confocal microscopy support was provided by staff at the University of Ottawa Cell Biology & Image Acquisition Core Facility. MAMT was supported by an Ontario Graduate Scholarship. This work was supported by operating grants to DJP from the Canadian Institutes of Health Research (MOP-97764, MOP-133586) and an operating grant from the Cancer Research Society, University of Ottawa, and Ottawa Hospital Research Institute partnership program.

**SUPPLEMENTARY INFORMATION****SUPPLEMENTARY MATERIALS AND METHODS*****PHF6 Knockdown***

Stable PHF6 shRNA knockdown cell lines were generated using the GIPZ PHF6 shRNA Viral Particle Starter Kit (Open Biosystems, VGH5526-EG84295). Briefly, HEK 293T cells, seeded the day before transduction at  $5 \times 10^4$  cells per well, were transduced for 6 hours at 37° C in serum-free media containing  $4 \times 10^4$  lentivirus particles and 8  $\mu\text{g}/\mu\text{L}$  polybrene then allowed to recover in growth media (DMEM, 10% FBS, 1% penicillin-streptomycin) for 72 hours, prior to selection in 1.5  $\mu\text{g}/\mu\text{L}$  puromycin. The following antisense sequences were used for PHF6 shRNA mediated knockdown: KD #1 (5'-TCAAAGTCTCCAAATTCTG, catalogue # V2LHS\_138602), KD #2 (5'-TTTCCTCGTTTAATCTCCT, catalogue # V3LHS\_350404), and KD #3 (5'-AAAAC TTTCTTCTAAATCA, catalogue # V3LHS\_350403). PHF6 knockdown was confirmed both by qRT-PCR (Figure 4-S3B) and Western blot (Figure 4-S3C). HEK 293T cell lines stably infected with the empty GIPZ vector were used as a negative control.

***Western blotting***

Transformed HEK 293T cells were harvested on ice and lysed in radioimmunoprecipitation assay buffer (RIPA; 50 mM Tris HCl pH 7.8, 150 mM NaCl, 1% Nonidet P-40, 0.5% sodium deoxycholate, 0.1% sodium dodecyl sulphate), resolved by SDS-PAGE (3-8% Tris-Acetate Novex gel, Life Technologies), and transferred onto a PVDF membrane (Millipore). Membranes were blocked in 1X TBST with 5% milk for 2 hours at room temperature, then incubated with primary antibody for PHF6 (HPA001023,

Sigma, 1:5000 dilution) or  $\alpha$ -tubulin (T9026, Sigma, 1:10 000 dilution) overnight at 4°C in 1X TBST with 5% BSA. Following three 1X TBST washes, membranes were incubated with the appropriate anti-rabbit (A4914, Sigma) or anti-mouse (A5906, Sigma) secondary antibody (1:10 000 dilution) in blocking solution for 45 minutes at room temperature. Development of the membranes was achieved using enhanced chemiluminescence (GE Healthcare) and an SRX-101A (Raytech) film developer.

### ***Cell proliferation assay***

Transformed HEK 293T cell lines were seeded on 10 cm plates ( $10^5$  cells per plate) and cultured at 37° C. Cells were harvested by trypsin digest at 24 hrs (day 1), 48 hrs (day 2), 72 hrs (day 3), 96 hrs (day 4), and 120 hrs (day 5) after seeding and the concentration of viable cells for each sample was measured using the Vi-CELL XR system (Beckman Coulter). Cumulative population doubling was used to measure cellular growth rates with the following formula: counts per day =  $[\log(\text{day X concentration}) - \log(\text{day 1 concentration})] / \log(2)$ .

### ***BrdU pulse-chase cell cycle assay***

This BrdU protocol was adapted from (Huh et al., 2012). Briefly, stable HEK 293T cells expressing PHF6 shRNA (KD #1, KD#2, KD#3) or empty GIPZ vector were seeded at a confluency of  $2 \times 10^5$  cells on a 10 cm tissue culture plate and cultured for 48 hours at 37° C, then pulsed with 30  $\mu$ M BrdU for 1 hour at 37° C. Cells were provided three PBS washes to remove BrdU, then grown in fresh selection media and harvested at the following timepoints (measured upon BrdU removal): 0 hrs, 4 hrs, 8 hrs, 12 hrs, 16 hrs, 20 hrs, and 24 hrs. Cells were fixed in ice cold 70% ethanol and prepared for flow cytometry analysis as described (Huh et al., 2012; Stubbert et al., 2007), including

labeling with a 1:100 dilution of BrdU primary antibody (BD Biosciences, 347580), 1:500 diluted Alexa Fluor 488 secondary antibody, and propidium iodide (Sigma). Flow cytometry was performed using a Beckman Coulter FACS Station and data analysis was performed with Flowing software version 2.5.1 (04-Nov-2013, created by Perttu Terho at the Turku Centre for Biotechnology, <http://www.flowingsoftware.com/>).

**Figure 4-S1. PHF6 co-localizes with the nucleolar FC and partially co-localizes with the DFC.**

(A) To demonstrate the reversibility of the DRB treatment, HEK 293T cells were treated with 25  $\mu\text{g}/\text{mL}$  DRB for 2 hours and allowed to recover for 2 hours (DRB off). HEK 293T cells were also treated with 5  $\mu\text{g}/\text{mL}$  of  $\alpha$ -amanitin, an RNA pol II inhibitor, to confirm if the ActD-mediated nucleolar disassembly observed in Figure 4-2 was indeed specific to RNA pol I inhibition. Cells were then fixed and labeled with antibodies to PHF6 (green) and either UBF, FBRL, or NCL (red), then visualized by confocal microscopy. Cells were counterstained with DAPI to visualize nuclei. (B) HEK 293T cells were treated with either 25  $\mu\text{g}/\text{mL}$  DRB or 0.5  $\mu\text{g}/\text{mL}$  Act D for 2 hours. Cells were then fixed and labeled with antibodies to PHF6 (green) and COILIN (red), a marker for Cajal bodies. Representative cell images are shown. This supplementary figure is an accompaniment for Figure 4-2.

**Figure 4-S2. The nucleolar localization of PHF6 is RNA-dependent.**

(A, B) HEK 293T cells were digested with either DNase I (10  $\mu\text{g}/\text{mL}$ ) or RNase A (10  $\mu\text{g}/\text{mL}$ ) and compared with untreated cells by immunocytochemistry. Cells were immunofluorescently stained with antibodies to PHF6 (green) and counterstained with (A) Pyronin Y to label RNA, or (B) FBRL, a DFC marker. Treatment with RNase A results in the loss of PHF6 from the nucleolus, as indicated by the loss of co-localization between PHF6 and Pyronin Y. The efficacy of the RNase A treatment is confirmed by an accompanying reduction in Pyronin Y intensity. Conversely, nucleolar PHF6 expression is not affected following treatment with DNase I. Like PHF6, the nucleolar localization of FBRL is unaffected by DNase I digestion, yet severely reduced in the RNase A treatment. Representative cell images are shown. This supplementary figure is an accompaniment for Figure 4-3.

**Figure 4-S3. Characterization of the PHF6 overexpression and knockdown cell lines.** (A-C) PHF6 levels were quantified from overexpression (PHF6-NTAP, PHF6-CTAP) and shRNA knockdown cell lines (KD #1, KD #2, KD #3) using qRT-PCR (A, B) with primers to amplify PHF6 mRNA (normalized to GAPDH mRNA levels); and by Western blot (C) with antibodies directed against PHF6 and  $\alpha$ -tubulin (loading control). Note that the Flag-PHF6 protein is detected above the endogenous PHF6 band. (D, E) Cumulative population doubling values were calculated from cell counts for cell lines (D) overexpressing PHF6 (n=5), or (E) PHF6 shRNA knockdown (n=4). Bars represent standard error (\* $p$ <0.05, \*\* $p$ <0.01, two-tailed student's t-test). [OE = overexpression]

**Figure 4-S4. Flow cytometry cell cycle progression analyses and histograms of the BrdU-positive population during PHF6 knockdown.**

(A) Flow cytometry cell cycle progression analysis was performed in HEK 293T cells lines expressing either empty pGIPZ vector (control, n=4) or PHF6 shRNA (n=6). Graphs represent the percentage of BrdU-positive cells in the G<sub>1</sub>, S, and G<sub>2</sub>/M gates at the indicated time points after the moment of BrdU removal (0 hours), following a 1 hour pulse with 30  $\mu$ M BrdU in unsynchronized cells. Bars represent standard error (\*p<0.05, \*\*p<0.01, two-tailed student's t-test). (B) Representative histograms for each time point (control or PHF6 shRNA), demonstrating the relative proportions of BrdU positive cells (y-axis) with respect to the propidium iodide (PI)-labeled DNA content (x-axis).

**Figure 4-S5. Relative abundance of RNA transcripts quantified from the rDNA gene.**

(A) qRT-PCR products from Figure 4-4D,E were re-analyzed with normalization performed against pre-pRNA levels (primer set D product, -1017/-924) from the same RNA sample (n=5). The y-axis is logarithmic (base 10). (B) Quantification of rRNA (primer sets E-H) and non-coding IGS RNA (primer sets A-D) from the rDNA gene was performed for PHF6 shRNA knockdown cell lines (n=4) by qRT-PCR, as described in Figure 4-4D,E. Bars represent standard error (\*p<0.05, \*\*p<0.01, two-tailed student's t-test).

## 5. GENERAL DISCUSSION

### 5.1 Overview of Findings

The advent of next-generation sequencing technologies has greatly facilitated whole genome mutation screening in many human cancers. Consequently, chromatin remodeling proteins that were originally established in the etiology of rare human developmental diseases are now increasingly being identified as targets for oncogenesis (You and Jones, 2012). Fitting this paradigm, germline *PHF6* mutations remain the sole known cause of BFLS, a rare developmental disease that has been diagnosed in fewer than 30 families, yet somatic *PHF6* mutations were recently observed to occur with greater frequency in patients who have acquired T-ALL, AML, or CML (Chao et al., 2010; Li et al., 2013; Van Vlierberghe et al., 2010; Van Vlierberghe et al., 2011). One of these publications, demonstrating the presence of a novel H329Q missense mutation in a T-ALL patient, is presented in Chapter 2. This chapter further describes a pediatric BFLS patient with an R342X frameshift mutation who acquired T-ALL, corresponding to a T-ALL frequency of 3% among all BFLS families, indicating that germline *PHF6* mutations may confer susceptibility to leukemia.

In both BFLS and leukemia, *PHF6* mutations limit the function of the protein. Prior to the work presented in this thesis, the consequences of these mutations with respect to the onset of disease, and even the function of the PHF6 protein itself, were largely unknown. PHF6 was known simply to possess nuclear and nucleolar localization and was classified as a chromatin remodeling protein based on the homology of its zinc finger domains to similar domains in protein families such as MLL or JMJD2. Unlike these known chromatin remodelers, however, PHF6 lacks catalytic domains that could

serve as a means of identifying its function. Moreover the significance of its localization within both the nucleoplasm and nucleolus remained undefined. These concerns are addressed in the work presented in Chapters 3 and 4.

In order to identify a function for PHF6, an IP-MS/MS based proteomic screen was performed under the premise that the activities of its putative interaction partners could be attributed to PHF6 itself. Most notably, PHF6 was found to interact with multiple constituents of the NuRD chromatin remodeling complex, a transcriptional regulator that participates in lineage commitment during development, indicating that PHF6 may in fact be targeting NuRD to specific transcriptional targets. Enrichment of the PHF6-NuRD complex was restricted to the nucleoplasm, although the proteomic screen yielded putative interactions between PHF6 and several proteins involved in ribosome biogenesis and RNA splicing as well, suggesting the existence of distinct PHF6 complexes with different functional roles in the nucleoplasm and nucleolus.

The implication for having two subnuclear pools of PHF6 is the need for an intrinsic mechanism to shuttle PHF6 between the nucleus and nucleolus as required. The identification of PHF6 serine phosphorylation sites in the expanded mass spectrometry dataset (see Appendix A) provides one potential clue as to how such a mechanism might occur. In total, three phosphorylation sites were identified: S145, S154, and S155. Peptides were observed to be singly phosphorylated at either S154 or S155 alone, however S145 phosphorylation was only observed in combination with phosphorylation at S155. Each of these serine phosphorylation sites are documented in the literature and are particularly elevated during mitosis or in response to TCR signaling (Dephoure et al., 2008; Mayya et al., 2009). While definitive experiments to identify the responsible

kinases have not yet been performed, high throughput screens indicate that S145 is phosphorylated by Polo-like kinase 1 (PLK1) (Kettenbach et al., 2011). Supporting this putative mechanism is the fact that S145 is situated within a PLK1 consensus sequence and phosphorylation at S155 provides a binding site for the polo binding domain of PLK1 (PBD) (Elia et al., 2003; Nakajima et al., 2003). The Appendix A dataset and the literature show that S145 is never phosphorylated on its own, suggesting a mechanism whereby phosphorylation at S155 primes S145 for PLK1-mediated phosphorylation. Supporting this model, two studies demonstrated that PLK1 inhibition not only led to a decrease in S145/S155 phosphorylation, but also an accumulation of the singularly phosphorylated S155 peptide (Grosstessner-Hain et al., 2011; Kettenbach et al., 2011). Interestingly, another screen identified S155 as a candidate substrate for CDK2 phosphorylation (Chi et al., 2008). Moreover, roscovitine-mediated CDK2 inhibition interferes with the ability of PHF6 to localize to the nucleolus (Kustatscher et al., 2014). PLK1 and CDK2 are highly active during S and G<sub>2</sub> phase, when nucleolar size and the rate of ribosome biogenesis is higher relative to G<sub>1</sub> (Lapenna and Giordano, 2009; Montanaro et al., 2008), indicating that PHF6 may be recruited to compensate for the increased rates of rRNA synthesis that precede cytokinesis.

Interestingly, these phosphorylated residues are adjacent to an NoLS sequence, a motif that is thought to promote localization to the nucleolus through direct and/or indirect interactions with nucleolar material (e.g. nucleic acid or protein) (Emmott and Hiscox, 2009). In Chapter 4, further investigation of the nucleolar portion of PHF6 indeed indicated the requirement for RNA in the localization of PHF6 to the nucleolus. PHF6 was also observed to localize to the FC and DFC nucleolar subcompartments at

whose interface rRNA transcription occurs. ChIP-qPCR analyses were performed, demonstrating that PHF6 is bound to the rDNA TSS and gene body. Quantitative rDNA transcript analyses showed that PHF6 overexpression correlates with a decrease in rRNA levels and an increase in repressive IGS RNA levels, suggesting a role for PHF6 in limiting the rate of rRNA synthesis.

### ***5.2 Modelling PHF6 gene targets***

From Chapter 2 and other case studies of BFLS and leukemia, PHF6 has been classified as a developmental regulator and tumour suppressor. While PHF6 is ubiquitously expressed, it is particularly elevated in embryonic tissues, immature thymocytes, and in the postnatal brain/CNS (Van Vlierberghe et al., 2010; Voss et al., 2007). In Chapter 3, PHF6 was demonstrated to interact with the NuRD complex, a transcriptional regulator with several gene targets that influence embryogenesis, oncogenesis, neurogenesis, and hematopoiesis (Hendrich et al., 2001; Lai and Wade, 2011; Potts et al., 2011; Yoshida et al., 2008), and a later publication described the association of PHF6 with the PAF1 transcriptional elongation complex (Zhang et al., 2013). Thus it is possible that PHF6, as a member of these complexes, regulates its own gene targets. Therefore the identification of any such gene targets provides a better means of understanding the disease mechanisms underlying the BFLS and T-ALL phenotypes.

The NuRD core complex has the ability to catalyze ATP-dependent nucleosome remodeling and histone deacetylation at its gene targets through its CHD and HDAC subunits respectively (Tong et al., 1998; Zhang et al., 1998), but the transcriptional outcome of its targets is dependent upon its collective associations with other activators (e.g. P300) and repressors (e.g. LSD1) (Wang et al., 2009; Williams et al., 2004). Several

NuRD interactors also possess zinc finger domains with the ability to target the complex to gene targets through DNA sequence-specific interactions (e.g. IKAROS, SALL1, BCL11B) (Lauberth et al., 2007; Molnar and Georgopoulos, 1994; Tang et al., 2011; Yamashita et al., 2007). As such, the PHF6 ZaP domain was discussed in Chapter 3 as a potential mediator for the associations between PHF6, NuRD, and chromatin.

The ZaP domain contains an atypical PHD domain, which was speculated to interact with post-translationally modified histones, and a C2HC zinc knuckle, which was discussed as a potential interaction surface with the MTA NuRD subunits, similar to known associations by BCL11B, FOG-1, and SALL1. These other NuRD interactors also possess a conserved N-terminal 12 amino acid sequence that fits into the binding pocket of the  $\beta$  propeller of another NuRD subunit, RBBP4 (Lauberth and Rauchman, 2006; Lejon et al., 2011). Indeed, following the publication of Chapter 3, another group demonstrated that PHF6 amino acid residues 152-171 directly interact with RBBP4 and furthermore that this sequence is highly similar to the conserved 12 amino acid sequence from BCL11B, FOG-1, and SALL-1 (Liu et al., 2014). Moreover, this group determined that the second ZaP domain of PHF6 does not bind histones but in fact binds dsDNA, providing further support for the classification of PHF6 as a transcription factor.

As an initial means of identifying potential PHF6 gene targets, microarray hybridization and qRT-PCR analyses were performed upon RNA samples derived from HEK 293T cell lines expressing either PHF6 shRNA knockdown or PHF6 overexpression (see Appendix A). From these analyses, *SPARC* was identified as a candidate for PHF6 repression. *SPARC* encodes a secreted collagen-binding glycoprotein that counters cell adhesion by interfering with the manner in which cells interact with the

extracellular matrix (Bradshaw, 2009). While ubiquitous, *SPARC* levels are noticeably present among astroglial cells in the developing and postnatal brain (Mendis and Brown, 1994; Mendis et al., 1995; Vincent et al., 2008), and particularly elevated during obesity and in several cancers (Kos and Wilding, 2010). Indeed, as is the case with PHF6 mutations, *SPARC* upregulation correlates with reduced overall survival in AML (Alachkar et al., 2014; Patel et al., 2012). As such, *SPARC* makes for an exciting candidate in attempting to resolve the pathogenic phenotypes that accompany PHF6 mutations in both BFLS and leukemia.

The manner in which PHF6 regulates *SPARC* remains inconclusive. Luciferase reporter assays (see Appendix A) indicate that the putative mechanism for the PHF6-related *SPARC* repression does not occur through the *SPARC* promoter. These results illustrate the need for further in-depth ChIP sequencing to catalogue genomic binding sites for PHF6 in relevant tissues, as has been performed for other NuRD interactors such as IKAROS and BCL11B (Kastner et al., 2010; Novershtern et al., 2011).

From these studies, it has been demonstrated that such transcription factors can greatly influence the ability of NuRD to activate or repress its target genes. For instance, CD4 is normally activated by NuRD, but repressed by IKAROS-NuRD (Naito et al., 2007). In another example, ChIP-seq analyses showed BCL11B-NuRD to bind target genes that were repressed in DP thymocytes, yet activated in SP cells (e.g. *RUNX3*) (Kastner et al., 2010). A later study determined that BCL11B was being dephosphorylated and sumoylated to recruit P300, which in turn led to the activation of the previously repressed target gene (Zhang et al., 2012b). Interestingly, PHF6 has

multiple phosphorylation sites in the interaction domain with RBBP4, although it is unclear whether this affects its association with NuRD (Kettenbach et al., 2011).

In carrying out future PHF6 ChIP-seq analyses, it will be important to compare primary sets of PHF6 binding sites with PHF6 null RNA expression datasets as well as with known binding sites for NuRD subunits (e.g. CHD4, MBD3), many of which have already been characterized in the literature (Reynolds et al., 2012b; Yoshida et al., 2008; Zhang et al., 2012a). PHF6 binding patterns can also be correlated with DNA methylation and histone PTM patterns in future assessments defining the role of PHF6 in the transcriptional activation or repression of specific targets. The possibility for PHF6 to have NuRD-independent targets should also be recognized, as evidenced by its regulation of rDNA described in Chapter 4.

### ***5.3 Modelling the contribution of ribosome biogenesis to BFLS and leukemia***

While additional PHF6 gene targets await characterization, ChIP-qPCR and RNA expression data from Chapter 4 demonstrate that rDNA, whose synthesis accounts for as much as half of all cellular transcription (Hamperl et al., 2013), is a key target for PHF6 repression. Moreover, PHF6 was demonstrated to associate with RNA in the nucleolus, and several nucleolar proteins based on IP-MS/MS data. As such, nucleolar ribosome biogenesis represents a major cellular pathway in the disease pathologies of BFLS and leukemia following PHF6 loss.

Ribosome biogenesis rates positively correlate with nucleolar size. In general, proliferating cells possess large nucleoli to accommodate the metabolic requirements of successive passages through the cell cycle, and over the course of differentiation, rDNA genes become increasingly silenced in an allelic manner (Schlesinger et al., 2009). Not

surprisingly, cancer cells with large nucleoli correlate with poor clinical outcomes (Derenzini et al., 2009). Large nucleoli are also present in terminally differentiated cells that possess hypertrophic cytoplasmic volumes. In neurons, such nucleoli are necessary for supplying a sufficient amount of ribosomes to growing neurites to accommodate local demands for translation (Gomes et al., 2011). Indeed many developmental intellectual disability diseases (e.g. Cockayne syndrome, Rett syndrome) and acquired neurodegenerative disorders (e.g. Alzheimer's, Parkinson's) are associated with reduced levels of ribosome biogenesis (Hannan et al., 2013; Hetman and Pietrzak, 2012).

In Chapter 4, PHF6 overexpression yielded reduced rRNA levels. If indeed a repressor, PHF6 loss in T-ALL, AML, and CML is consistent with a model in which the hyperactivation of ribosome biogenesis is favoured. However such a role is not consistent with the paradigm of reduced ribosome biogenesis in intellectual disability diseases like BFLS. A similar paradox is represented by the loss of MeCP2, which is responsible for Rett syndrome (Amir et al., 1999). MeCP2 binds methylated CpG DNA, a mark for rDNA silencing (Santoro and Grummt, 2001), and contributes to heterochromatin formation (Brero et al., 2005); yet, rather than hyperactivating rRNA synthesis, its loss correlates with reduced nucleolar size (Singleton et al., 2011). In addressing this dilemma, it is important to consider the regulation of cell cycle checkpoints.

Reports in the literature identify PHF6 as a target of the ATM DNA damage checkpoint kinase (Matsuoka et al., 2007) and its loss correlates with the accumulation of phosphorylated  $\gamma$ H2AX (Van Vlierberghe et al., 2010; Wang et al., 2013). The ATM pathway has been shown to inhibit RNA Pol I (Kruhlak et al., 2007). Moreover, rDNA transcriptional stress activates other checkpoints that can shut down nucleolar activities,

trigger cell cycle arrest, or even induce apoptosis (Grummt, 2013). Notably, the pRB and p53 master checkpoint proteins are key negative regulators of rRNA transcription (Montanaro et al., 2008). Interestingly, the p53 guardian protein MDM2 is immobilized in the NoDP by non-coding IGS transcripts, including IGS<sub>36</sub>RNA, under conditions of transcriptional stress (Audas et al., 2012). Thus, altered levels of PHF6 may instigate DNA repair or cell cycle checkpoint mechanisms in the absence of secondary mutations.

The epigenetic landscapes of cancers such as T-ALL and AML are defined by frequent and co-occurring mutations to favour both unrestricted proliferation and tumour survival (Cancer Genome Atlas Research, 2013; Van Vlierberghe et al., 2008). In T-ALL, *PHF6* mutations co-occur with mutations in *TLX1*, *TLX3*, *NOTCH1*, *JAK1*, as well as *SET-NUP214* translocations (Van Vlierberghe et al., 2010; Wang et al., 2011). In AML, *PHF6* mutations co-occur with *RUNX1* mutations (Cancer Genome Atlas Research, 2013). While the advantages conferred by these co-occurring mutations in specific T-ALL/AML lineages is not yet clear, this pathogenic model is similar to the example provided by *BCL11B* in developing thymocytes, in which the loss of *BCL11B* on its own induces massive apoptosis during  $\beta$ -selection (Wakabayashi et al., 2003), yet also favours T-ALL progression when lost in combination with other oncogenically favourable events (De Keersmaecker et al., 2010).

Taken together, the presence of established checkpoints may explain how a loss of rDNA repression causes reduced ribosome biogenesis in developing tissues, yet hyperactivates ribosome biogenesis in cancer cells with deactivated checkpoints. It is worth noting that the contribution of *PHF6* mutations towards other forms of neoplasia has not yet been well investigated, however in contrast to T-ALL and AML, the shRNA-

mediated depletion of *Phf6* in a murine B-ALL model corresponded to a reduction in the rate of tumorigenic growth (Meacham et al., 2015). As such, these results suggest the downstream functions of PHF6 are variable among different cell types, or perhaps there are differences in the cell cycle or developmental checkpoints that become compromised in combination with *PHF6* loss-of-function in T-ALL and AML vs. B-ALL or other forms of neoplasia. Thus, future investigations need to be considerate of the potential for the PHF6 protein to have tissue-specific functional roles or for its expression to be subject to different tissue-specific regulatory mechanisms.

#### ***5.4 Developing biological therapies for BFLS and T-ALL***

In working towards future therapies for BFLS, T-ALL, AML, and CML, future research needs to utilize mammalian models so that the loss of PHF6, and the subsequent impact on gene expression or ribosome biogenesis, can be studied in populations of primary cells that are relevant to the onset of disease. Even though many developmental features are established by birth, much of the developmental delay among BFLS patients only becomes apparent postnatally (Gecz et al., 2006), perhaps indicative of the importance of nucleoli toward supporting post-mitotic neuronal activities and the potential for some level of rescue. Such optimism is reinforced by recent publications in which neurological deficits were partially rescued with statins in mouse models for both Rett syndrome and Fragile X syndrome (Buchovecky et al., 2013; Osterweil et al., 2013), as well as the existence of ongoing clinical trials of mGluR5 antagonists in the treatment of Fragile X (Jacquemont et al., 2014; Pop et al., 2014)

In treating leukemia, identifying established gene targets may represent new pathways for inhibition. In fact, SPARC and the HDAC subunits of NuRD are known

targets for bortezomib and SAHA, respectively (Alachkar et al., 2014; Finnin et al., 1999). Novel anti-cancer therapeutics that target ribosome biogenesis have also recently been developed, including CX-5461 and BMH-21, which act by repressing RNA Pol I and stimulating p53-dependent apoptosis (Bywater et al., 2012; Peltonen et al., 2014).

### ***5.5 Conclusion***

The body of work in this thesis includes the first description of a BFLS patient to develop T-ALL, the first identification of a protein complex (NuRD) that associates with PHF6, the first endogenous CHIP-qPCR mapping of PHF6 binding sites across the rDNA gene, and the first demonstration of RNA-dependent localization of PHF6 to the nucleolar FC/DFC. Taken together, these data present a model whereby PHF6 executes its function through participation in the transcriptional regulation of mRNA and rRNA gene targets.

## Contributions of Collaborators

The design, performance, analysis, and interpretation of all experimental work was carried out by Matthew A.M. Todd, unless otherwise specified. This thesis was written and prepared by Matthew A.M. Todd and edited by David J. Picketts, with the following exceptions: Chapter 2 was jointly written by Christian P. Kratz and Dr. David J. Picketts; Appendix B was written by David J. Picketts; Appendix C was jointly written by Matthew A.M. Todd and Michael S. Huh, with editing by David J. Picketts; and Appendix D was written by Matias Alvarez-Saavedra and David J. Picketts.

Some work presented in this thesis was generated with the help of collaborators. In Chapter 2, Mwe Mwe Chao (Children's National Medical Center, Washington DC) characterized the clinical features of the BFLS patient shown in Figure 2-1, Udo Kontny (University of Freiburg, Germany) provided lymphoblast patient DNA, and Lemuel Racacho operated the DNA sequencing instrument. In Chapter 3, Michael Rudnicki and Iain McKinnell provided the pBRIT-LoxP-NTAP and pBRIT-LoxP-CTAP vectors, while Jozef Gécz (University of Adelaide, Australia) provided the monoclonal PHF6 antibody. In Chapter 4, Michael S. Huh performed the Pyronin Y staining for Figure 4-S2A.

In Appendix A, Keqin Yan and Alan J. Mears executed the microarray analyses, while Matthew A.M. Todd annotated the data and prepared Table A-2. Also, the pGL4.11 and pGL4.11-SPARC plasmids used in Figure A-4 were provided by Dr. Guido Marcucci (The Ohio State University Comprehensive Cancer Center), while the pGL4.74 plasmid was provided by Dr. Valerie Wallace. The contributions for Appendices B and D are indicated on pages 187 and 209 respectively.

# **APPENDIX A**

## **Additional Data**

**SUMMARY*****Chapter 3: Detecting phosphorylation of PHF6 serine residues from mass spectra***

Several putative PHF6 phosphorylation sites have been identified in the literature through high throughput mass spectrometry-based screens (Dephoure et al., 2008; Matsuoka et al., 2007; Mayya et al., 2009; Olsen et al., 2010). As such, additional parameters of the MASCOT analysis of the mass spectra from the IP-MS/MS experiment in Chapter 3 allowed for the identification of phosphorylated and ubiquitylated peptides. Table A-1 shows all PHF6 phosphopeptides detected within the dataset. Phosphorylated PHF6 peptides were found to either be singularly phosphorylated at S154 or S155, or dually phosphorylated at S145 and S155.

**Table A-1. List of phosphorylated PHF6 peptides from IP-MS/MS experiment (see Table 3-1).**

**Chapter 3: Tandem affinity purification (TAP)**

The initial objective of Chapter 3 was to pull down PHF6 interaction partners using TAP (Figure A-1), rather than 3X Flag alone, which has been described (Puig et al., 2001). PHF6-CTAP was nearly completely captured on the M2-Flag beads, as evidenced by the absence of PHF6-CTAP in the first flowthrough lysate (lanes 1-3, Figure A-1A,B). Endogenous PHF6 was not captured, indicating that PHF6-CTAP does not interact with PHF6. The TEV cleavage was also very efficient at eluting recombinant PHF6 from the M2-Flag beads (see lanes 4-7). TEV cleavage also induced a mass shift, as predicted (PHF6-CTAP is 47 kDa, TEV-cleaved PHF6-CTAP is 45 kDa). For the second capture step, recombinant PHF6 was nearly completely captured by the Ni-NTA beads through its 6x His tag (lanes 8-9). Also, the final elution of recombinant PHF6 was very efficient (lanes 10-11). When the TAP purification was scaled up to a starting material of 50 mg nuclear lysate, TAP-purified recombinant PHF6 could easily be visualized by colloidal blue Coomassie (Figure A-1C), and mass spectrometry-based protein identification of the gel slice corresponding to recombinant PHF6 detecting similar sequence coverage to the results presented in Table 3-1. However, the mass spectrometry analysis did not detect significant quantities of peptides for any other proteins (not shown). Following these experiments, it was speculated that of NTA (nitrilotriacetic acid) might be stripping the zinc ions from the ZaP domains of PHF6, based on its high affinity for zinc in other proteins (Schullek and Wilson, 1988). If so, the resulting collapse of the ZaP domains may cause PHF6 to lose its interaction partners. Therefore, the 6x His-tag purification step of the TAP protocol was determined to be too stringent, and 3x Flag purification alone was employed for the IP-MS/MS experiments presented in Chapter 3.

**Figure A-1. Tandem affinity purification of PHF6-CTAP in HEK 293T cells.**

(A) Schematic diagram for the analysis of PHF6-CTAP and empty vector control samples analyzed by immunoblotting with anti-PHF6 in (B). Pre-cleared nuclear lysates were incubated with M2-Flag agarose beads overnight, then the beads were separated into four equal fractions (#1-4) which were each halted at different steps within the TAP procedure to #1) assess the efficiency of protein capture with the M2-Flag beads (lanes 1-3), #2) assess the efficiency of TEV cleavage (lanes 4-5), #3) assess how much PHF6-CTAP remains bound to the beads after incubating with TEV (lanes 6-7) and to test the efficiency of protein capture with the Ni-NTA beads (lanes 8-9), and #4) to assess the efficiency of the elution (lanes 10-11). Highlighted circles correspond to lanes where PHF6-CTAP is expected to be found. The predicted masses are 42 kDa for PHF6, 47 kDa for PHF6-CTAP, and 45 kDa for PHF6-CTAP after TEV cleavage. FT1 and FT2 refer to the flowthrough, or unbound fraction, after each binding step. Lanes 1 and 3 contain 20  $\mu$ g of lysate, and total sample was loaded for lanes 2 and 4-11. (C) Colloidal Blue Coomassie stain of purified TAP products from HEK 293T cells expressing empty vector or PHF6-CTAP (~50 mg of nuclear lysate for each sample prior to TAP purification).

**Chapter 3 follow-up: Identifying PHF6 gene targets**

Chapter 3 describes the interaction between PHF6 and NuRD in the nucleoplasm as well as the nucleolar associations of PHF6. While Chapter 4 goes on to further dissect the nucleolar activities of PHF6, Appendix A describes additional experiments that were performed with the objective of identifying PHF6 gene targets.

To identify potential gene targets, RNA from a HEK 293T cell line overexpressing PHF6 (PHF6-CTAP) and a cell line expressing empty vector was hybridized to a HEEBO microarray, identifying 285 genes with a 2-fold expression change when PHF6 is overexpressed. Gene ontology was performed on the gene list, identifying 22 candidates, summarized in Table A-2, having shared biological processes with PHF6 (e.g. brain development, hematopoiesis, obesity, limb bud development, or association with T-cell and/or myeloid leukemia). Several of these candidates are involved in the regulation of cell proliferation, signal transduction, and cell adhesion/migration processes, however it was unclear which genes could represent direct targets for PHF6 and which genes may simply be upregulated/downregulated in response to the cellular stress induced by overexpressing PHF6.

To increase the probability of identifying direct gene targets, the gene candidates listed in Table A-2 were subjected to validation by qRT-PCR analysis in PHF6 shRNA knockdown and overexpression cell lines (Figure A-2). It was reasoned that direct targets would be upregulated during PHF6 knockdown and downregulated by PHF6 overexpression, and vice versa. The genes with transcript expression levels matching this prediction included *LY6G6D*, *SPARC*, and *EPHB2*. In addition, while *UBF* was not

**Table A-2. Gene expression changes resulting from the overexpression of PHF6.\***

\*Note: negative fold changes denote downregulation.

detected in the microarray dataset, its levels appear to negatively correlate with those of PHF6, consistent with observations from the literature (Wang et al., 2013).

To further validate the biological relevance of these candidate gene targets to PHF6, gene expression was quantified in lymphoblast cell lines derived from BFLS patients and wild type controls (Figure A-3). BFLS patient #1 has an R257G missense mutation and BFLS patients #2 and #3 are siblings that express PHF6 $\Delta$ exon3 (Vallee et al., 2004). Western blotting with anti-PHF6 demonstrates reduced or absent protein levels of PHF6 in all three BFLS patients, but not the controls (Figure A-3A), while PHF6 mRNA transcripts are only reduced in BFLS patients #2 and #3 (Figure A-3B). From these data, *SPARC* was the only target gene candidate with expression levels in the BFLS cell lines that were most consistent with the observations from Figure A-2, however it should be noted that BFLS patient #3 did not have significantly upregulated *SPARC* levels in comparison to the controls. While *TMEPAI* levels were also elevated in all three BFLS patients, *SPARC* was selected as a candidate for further analyses due to its many shared biological processes with PHF6 (see Table A-2).

*SPARC*, also known as BM-40 or osteonectin, is a secreted collagen-binding glycoprotein that influences the binding of the cell surface to the extracellular matrix. When *SPARC* levels increase, the extracellular matrix becomes more fibrotic and cell adhesion is reduced (Bradshaw, 2009). In humans, enhanced expression of *SPARC* correlates with the onset of obesity and more aggressive tumour growth in AML (Alachkar et al., 2014; Kos and Wilding, 2010). Collectively, the microarray and qRT-PCR data is consistent with a model whereby PHF6 represses *SPARC*, however it remains to be determined how PHF6 specifically influences *SPARC* expression.

**Figure A-2. Validation of PHF6 target genes by qRT-PCR in HEK 293T cells.**

(A,B) RNA was harvested from HEK 293T cells expressing PHF6 shRNA or cells overexpressing PHF6, then subjected to qRT-PCR analysis to validate gene expression changes observed from the microarray results shown in Table A-2. Fold changes are represented relative to empty vector controls. GAPDH was used as a reference gene. Bars represent standard error (n=3, \*p<0.05, \*\*p<0.01, two-tailed student's t-test). The y axis is logarithmic (base 2).

**Figure A-3. Validation of PHF6 target genes by qRT-PCR in BFLS patient lymphoblasts.**

(A) Western blotting with antibodies directed against PHF6 and  $\alpha$ -tubulin (loading control) in RIPA lysates from control and BFLS patient lymphoblasts. BFLS patient #1 has a R257G mutation while patients #2 and #3 are siblings that express PHF6 $\Delta$ exon3. BFLS patients #1, #2, and #3 are loaded in sequential order from left-to-right where indicated. (B,C) RNA was isolated from BFLS patient lymphoblasts and subjected to qRT-PCR to validate gene expression changes observed in HEK 293T-derived cell lines. Bars represent standard error (n=3, \*p<0.05, \*\*p<0.01, two-tailed student's t-test). The y axis is logarithmic (base 2).

The *SPARC* promoter (-651/1) region already possesses known binding sites for transcriptional activation by SP1, NF $\kappa$ B, and BRG1 (Alachkar et al., 2014; Xu et al., 2010b). Moreover RUNX1, which is mutated with PHF6 in both T-ALL and AML (Cancer Genome Atlas Research, 2013; Grossmann et al., 2013) and has also recently been linked with developmental intellectual disability (Katzaki et al., 2010), potentially represses *SPARC* through binding to this promoter (Alachkar et al., 2014).

To determine if PHF6 directly (e.g. PHF6-NuRD binding) or indirectly (e.g. affecting the recruitment of SP1, NF $\kappa$ B, BRG1, or RUNX1) modulates *SPARC*, a luciferase assay was performed by transfecting the pGL4.11 Firefly luciferase plasmid containing the (-651/1) *SPARC* promoter region, or empty vector, into HEK 293T cell lines expressing PHF6 shRNA knockdown or PHF6 overexpression. If PHF6 was indeed repressing *SPARC*, it was expected that the knockdown condition would elicit higher luciferase activity and that PHF6 overexpression would result in a reduction of luciferase activity. As shown in Figure A-4, PHF6 knockdown had no impact on luciferase expression in comparison to the control, while PHF6 overexpression was actually higher for the cell line expressing PHF6-CTAP in comparison to the control.

Thus it was concluded that the means by which PHF6 represses *SPARC* does not occur through binding to the proximal promoter nor by specifically altering the binding of other *SPARC* transcription factors to this region. Future work should focus on identifying PHF6 binding sites by ChIP-sequencing. It is perhaps possible that PHF6 may instead bind *SPARC* coding sequences, which would be consistent with its binding along the rDNA gene, shown in Chapter 4, and with its association with PAF1 in the transcriptional regulation of NGC/CSPG5 (Zhang et al., 2013).

**Figure A-4. PHF6 does not induce luciferase repression through the -651/1 SPARC promoter gene element.**

Mean ratios (n=3) of Firefly luciferase (RLUS1) to *Renilla* luciferase (RLUS2) levels that were quantified in either (A) PHF6 overexpression (OE) cell lines or (B) PHF6 shRNA knockdown cell lines. Cell lines were transfected with either the empty luciferase vector (pGL4.11) or a plasmid expressing the -651/1 region of the SPARC promoter (pGL4.11-SPARC). Bars represent standard error (\*p<0.05, \*\*p<0.01, two-tailed student's t-test).

## **MATERIALS AND METHODS**

### ***Cell culture, RNA extractions, and Western blot***

See Chapters 3 and 4 for a description of the generation of PHF6 overexpression and knockdown HEK 293T-derived cell lines, as well as the necessary cell culture conditions. BFLS patient lymphoblast cell lines #1 (R257G), #2 (PHF6 $\Delta$ exon3), and #3 (PHF6 $\Delta$ exon3), and control lymphoblast cell lines have been previously described (Vallee et al., 2004), and were cultured in RPMI-1640 (Sigma), supplemented with 20% FBS and 1% penicillin-streptomycin. In preparation for the RNA extractions, HEK 293T-derived cell lines were seeded at a confluency of  $2 \times 10^5$  cells per 10 cm tissue culture dish and incubated at 37° C for 48 hours, while  $5 \times 10^5$  lymphoblasts were seeded per 75 mm<sup>2</sup> tissue culture flask and incubated at 37° C for 48 hours. RNA extractions were performed using the RNeasy Mini Kit (Qiagen). Additionally, for lymphoblast cell lines, protein extractions and Western blotting were performed as described in Chapter 4.

### ***Tandem affinity purification (TAP)***

HEK 293T nuclear lysates from cells expressing empty vector or PHF6-CTAP were prepared for TAP, a two-step purification method that allows for the high yield purification of protein complexes under native buffer conditions (Puig et al., 2001). The TAP tag expressed in these cell lines consists of a C-terminal 6X His tag, a tobacco etch virus (TEV) sequence, and a 3X Flag tag (see Chapter 3). TAP purification was performed similarly to the 3X Flag purification described in Chapter 3, with the following changes: elution from the M2-Flag beads was performed using two 3 hr elutions at 4° C in the presence of 10U (per mg lysate) of AcTEV protease (Invitrogen) in binding buffer, to cleave the TEV site. Both eluted fractions were combined, then

incubated with 60  $\mu$ L Ni-NTA bead slurry (50%) for 3 hours at 4° C with rotation in binding buffer containing 20 mM imidazole (Sigma). Ni-NTA beads were then given 5 x 5 min washes in binding buffer containing 20 mM imidazole, then captured protein complexes were eluted with 200 mM EDTA in binding buffer. Eluted products were concentrated by centrifugal filtration (MWCO 10 kDa Microcon, Millipore). Fractions were collected for each step of the purification and analyzed by Western blot, as indicated in Figure A-1A,B. Bead stripping was performed in a 1:1 mixture of 2X Novex buffer (Invitrogen) and binding buffer (with 100  $\mu$ M DTT added). Final TAP products were also visualized by colloidal blue Coomassie (Invitrogen) (Figure A-1C).

### ***Gene expression (microarrays)***

RNA from HEK 293T cell lines stably expressing empty vector (pBRIT-LoxP-NTAP) or overexpressing for PHF6 (PHF6-CTAP) were respectively labelled with Cy3 or Cy5 using a 3DNA Array 900 kit (Genisphere), then co-hybridized to a HEEBO gene expression array (Microarrays Inc., HS1100). Two replicates were performed, with the dyes flipped between control and PHF6-CTAP RNA for the second replicate to counter dye bias. Probe-specific signals were quantified with ScanArray express (Perkin Elmer), and the WEBARRAY online tool (<http://www.webarraydb.org/webarray/index.html>) was used for data processing and statistics. The following thresholds were applied to the finalized dataset to score a given probe (gene) as being differentially expressed during PHF6 overexpression:  $A > 9$ ,  $M > 0.32$  or  $M < -0.32$ , and  $p < 0.01$ . Note:  $M = \log_2$  ratio of PHF6-CTAP/control signal and  $A = \log_2$  average signal strength. Biological processes were attributed to candidate genes by screening the final gene list against publically

available gene ontology datasets with AmiGO 2 software (<http://geneontology.org/>), and by performing PubMed searches for individual genes.

### ***Quantitative real-time PCR***

Reverse transcription and qRT-PCR were performed as described in Chapter 4. All primers (with corresponding annealing temperatures) are listed in Table A-3. Fold changes were calculated with the  $\Delta\Delta C_t$  method using GAPDH as an internal control. For gene expression analyses from HEK 293T-derived cell lines, three PHF6 shRNA knockdown cell lines (KD #1, KD #2, KD #3; see Chapter 4 supplementary information) were analyzed (three technical replicates each) for a biological  $n = 3$ , while three technical replicates of the PHF6-CTAP overexpression cell line are presented as a technical  $n = 3$  in Figure A-2. For gene expression analyses from BFLS patient cell lines, three technical replicates were performed for each BFLS patient (#1, #2, #3) for a technical  $n = 3$ . In each technical replicate, fold changes for genes expressed by individual BFLS patient were calculated using an average  $\Delta C_t$  from four control patients that each expressed wild type PHF6. Statistical analyses were performed in Microsoft Excel. Two-tailed t tests, 95% confidence intervals, and 99% confidence intervals were used to determine significance.

### ***SPARC promoter luciferase assay***

HEK 293T-derived PHF6 overexpression and knockdown cell lines were seeded at ~80-90% confluency in 6-well tissue culture plates and each well was transfected with 2  $\mu\text{g}$  of a pGL4.11 Firefly luciferase plasmid, expressing either the -651/1 region of the SPARC promoter (pGL4.11-SPARC) or empty vector (pGL4.11), in a 1.2 mL volume for 6 hours at 37° C with Lipofectamine 2000 (Life Technologies) according to the

manufacturer's protocol (Alachkar et al., 2014). As a control, all cells were co-transfected with 10 ng of the pGL4.74 Renilla luciferase plasmid. At 72 hours post-transfection, cells were washed with PBS and luciferase reactions were prepared using the Dual-Luciferase Assay Kit (Promega) according to the manufacturer's protocol, and luciferase signals were quantified on a Lumat LB 9507 luminometer (Eg&G Berthold) to measure Firefly luciferase activity (RLUS1) and Renilla luciferase activity (RLUS2). Two-tailed t tests and 95% confidence intervals were used to determine significance.

### Abstract

**Background:** Mutations in genes whose products modify chromatin structure have been recognized as a cause of X-linked mental retardation (XLMR). These genes encode proteins that regulate DNA methylation (*MeCP2*), modify histones (*RSK2* and *JARID1C*), and remodel nucleosomes through ATP hydrolysis (*ATRX*). Thus, genes encoding other chromatin modifying proteins should also be considered as disease candidate genes. In this work, we have characterized the *SNF2L* gene, encoding an ATP-dependent chromatin remodeling protein of the ISWI family, and sequenced the gene in patients from 12 XLMR families linked to Xq25-26.

**Methods:** We used an *in silico* and RT-PCR approach to fully characterize specific *SNF2L* isoforms. Mutation screening was performed in 12 patients from individual families with syndromic or non-syndromic XLMR. We sequenced each of the 25 exons encompassing the entire coding region, complete 5' and 3' untranslated regions, and consensus splice-sites.

**Results:** The *SNF2L* gene spans 77 kb and is encoded by 25 exons that undergo alternate splicing to generate several distinct transcripts. Specific isoforms are generated through the alternate use of exons 1 and 13, and by the use of alternate donor splice sites within exon 24. Alternate splicing within exon 24 removes a NLS sequence and alters the subcellular distribution of the *SNF2L* protein. We identified 3 single nucleotide polymorphisms but no mutations in our 12 patients.

**Conclusion:** Our results demonstrate that there are numerous splice variants of *SNF2L* that are expressed in multiple cell types and which alter subcellular localization and function. *SNF2L* mutations are not a cause of XLMR in our cohort of patients, although we cannot exclude the possibility that regulatory mutations might exist. Nonetheless, *SNF2L* remains a candidate for XLMR localized to Xq25-26, including the Shashi XLMR syndrome.

## Background

The isolation of genes underlying X-linked mental retardation (XLMR) disorders has been hampered, in part, by the broad phenotypic variability observed in patients that restricts linkage analysis to large single families or instances where a specific trait facilitates phenotypic splitting. More recently, the use of large scale genomic methods including comparative genome hybridization (CGH) arrays and patient sequencing projects has increased the identification rate of XLMR disease genes. Surprisingly, each gene identified accounts for a small proportion of cases and there remain many conditions for which a gene has not been identified. Nonetheless, several trends have emerged. These include the identification of XLMR genes encoding proteins that modulate chromatin structure [1]. The cloning of the *ATRX* gene as the cause of the  $\alpha$ -thalassemia mental retardation (ATR-X) syndrome established the paradigm for chromatin remodeling proteins in neurodevelopmental disorders [2]. This gene, encoding a SWI/SNF-like protein, is also mutated in other severe XLMR syndromes lacking  $\alpha$ -thalassemia and in patients with mild-to-moderate XLMR [3]. Subsequently, the *RSK2* gene encoding a histone kinase was identified as the causative gene for Coffin-Lowry syndrome and non-specific XLMR [4,5], and the methyl-CpG-binding protein 2 (*MeCP2*) gene was identified as the causative gene for Rett syndrome [6] and other non-specific male MR [7-9]. More recently, the *PHF6* (Borjeson-Forsman-Lehmann syndrome; [10]), *ZNF41* [11], *ZNF81* [12], and *JARID1C* [13] genes have also been implicated in XLMR and have roles in transcriptional regulation and/or chromatin remodeling. Taken together, these studies suggest that additional chromatin interacting proteins whose genes reside on the X chromosome should be considered as disease candidates for both syndromal and non-specific XLMR disorders.

The *Drosophila* ISWI gene was identified as a distinct SWI/SNF subclass named the Imitation SWI (ISWI) family [14]. Two human orthologs of *Drosophila* ISWI (dISWI) have been described, *SNF2H* (SMARCA5) which maps to 4q31.1 and *SNF2L* (SMARCA1) which maps to Xq25-26 [15,16]. Moreover, analysis of the murine *Snf2h* and *Snf2l* genes demonstrated that *Snf2h* was expressed in proliferating neuroblast layers whereas *Snf2l* expression was enhanced in differentiating neuronal populations [17]. Indeed, purification of the SNF2L-containing human NURF complex demonstrated that it regulated expression of the *engrailed* genes, which are important in mid/hind-brain development [18]. In addition, the latter study also demonstrated that SNF2L could promote neuronal differentiation when expressed ectopically in neuroblasts [18]. SNF2L was also found to be a component of a second chromatin remodeling complex, called CERF that contains the CECR2 protein, a transcription factor involved in

neurulation and a cause of exencephaly in mice when mutated [19]. These studies suggest that *SNF2L* is an excellent candidate gene for the cause of XLMR. In this study, we have characterized multiple splice forms and examined 12 families with XLMR for mutations in *SNF2L*.

## Methods

### Reverse Transcription-PCR

For cell lines, total RNA was prepared from cell lines by acid phenol extraction of cell lysates [20]. Poly A+ RNA for reverse transcription was purified from total RNA using the PolyATtract mRNA Isolation System (Promega, Nepean, Ontario). Total RNA from human tissues and specific brain regions were obtained commercially (Applied Biosystems Canada, Streetsville, Ontario). Total RNA (2  $\mu$ g) or Poly A+ RNA (100 ng) was reverse transcribed using Superscript RT (Invitrogen) and a combination of oligo dT and random hexamers. PCR reactions for analysis of *SNF2L* splice variants were at 94°C for 30 seconds, 53°C for 30 seconds and 72°C for 2 minutes for 35 cycles, followed by a final extension of 15 minutes at 72°C. For the 5' splice variants, the following primers were used: 5'UTR SNF2L1 Fwd, 5' CAACTTGCTGCTAAAGCGCC 3'; 5'UTR SNF2L2 Fwd, 5' GGAATTCATGGAGCAGGACACTGC 3'; SNF2L5'splice variants Rev, 5'CACCAAGACAATTTTAGTG 3'. For the NLS splice variants: SNF2L NLS Fwd, 5' GGAGGTCATGGAGTATTC 3' and SNF2L NLS Rev, 5'CAGTAGCTGACTCTGCTTTCTTTTCTGTG 3'.

### Patient Material

DNA samples from 12 individuals affected with XLMR and previously mapped to a region encompassing the *SNF2L* gene were used for direct sequencing analysis. Samples from families F85-19 [21], F93-04, and F91-02 were provided by Drs. Ben Hamel and Hans van Bokhoven (University Hospital Nijmegen, Nijmegen, Netherlands). Samples K8045 [22], K8135 [23], K8320, K8395, K8725, K8895 [24], and K8923 were generously provided by Dr. Charles Schwartz (JC Self Research Institute, Greenwood Genetic Center, Greenwood South Carolina). The non-syndromic XLMR sample 24981 was provided by Dr. Judith Allanson (Children's Hospital of Eastern Ontario, Ottawa Ontario). The Pettigrew syndrome DNA sample was prepared from a commercially available EBV transformed lymphoblast cell line (GM12523; Coriell Cell Repository, Camden, NJ).

### Plasmid constructs

The SNF2L NLS splice variants were cloned into the pcDNA3 expression plasmid (Invitrogen Canada Inc. Burlington, ON), each with an amino terminal tag encoding the FLAG epitope. Annealed primers encoding the FLAG epitope were inserted in the *KpnI* and *EcoRI* sites of the pcDNA3 plasmid. The 5' region encoding the amino ter-

minus of the SNF2L2 splice variant (SNF2LB) was engineered with an *EcoRI* restriction site for cloning in frame with the FLAG epitope. The primers used were: FLAG-sense *EcoRI*, 5'-CCCACCATGGATTACAAGGATGACGACGATAAGG-3' and FLAG-antisense *EcoRI*, 5'-AATTCCTTATCGTCGTCATCCTTGTAATCCATGGTGGGGTAC-3'. The remainder of each cDNA (+ NLS or - NLS) was inserted in two additional cloning steps to construct plasmids encoding full length SNF2L proteins with and without a nuclear localization signal.

#### Cell transfections and immunofluorescence

293HEK cells were cultured in EMEM (Eagle's Minimal Essential Medium, Wisent, St Bruno, Quebec) supplemented with 10% fetal bovine serum (FBS) in a humidified 95% air with 5% CO<sub>2</sub> incubator at 37°C. One day prior to transfection, cells were plated on glass coverslips coated with poly D-lysine (100 µg/ml, Sigma, Oakville, Ontario) in 6 well tissue culture plates at a density of approximately 3 × 10<sup>5</sup> cells/well. Cells were transfected with 5 µg DNA [pcDNA3 control, pcDNA3 FLAG-SNF2LANLS, or pcDNA3 FLAG SNF2L] and the Lipofectamine 2000 reagent (Life Technologies, Burlington, Ontario) according to the manufacturer's protocol. After 48 hours, cells were fixed in cold ethanol/methanol (3:1) prior to blocking with 10% FBS diluted in PBS. Coverslips were incubated with diluted primary antibody (murine anti-FLAG monoclonal clone M2, 2 µg/ml, Sigma, Oakville, Ontario) for 1 hour at room temperature, washed and then incubated for 1 hour at room temperature with FITC-conjugated donkey-anti-murine IgG secondary antibody (Sigma) diluted 1:100 in PBS. Cell nuclei were counterstained with 1 µg/ml DAPI (Sigma) and images were captured using a Zeiss Axioplan 2 microscope outfitted with an AxioCam camera and AxioVision software.

#### SNF2L Mutation Analysis

Genomic DNA from individuals affected with XLMR in each of the 12 families analyzed was used to amplify each exon of the *SNF2L* gene with forward and reverse primers that annealed to flanking intron sequences, approximately 100 bp from each exon/intron boundary (primer sequences available upon request). Genomic DNA from an individual unaffected by XLMR was the control for all PCR reactions. For each reaction, 100–200 ng DNA was combined with 1 µM each of forward and reverse PCR primers, 200 µM dNTPs, 2.5 mM MgCl<sub>2</sub>, 20 mM Tris-HCl pH 8.4, 50 mM KCl, and 1 unit Taq DNA polymerase in a volume of 100 µl. PCR reactions were incubated at 95°C for 40 seconds, 57°C for 40 seconds and 72°C for 3 minutes for 30 cycles, followed by a final extension of 15 minutes at 72°C. DNA obtained from PCR reactions was purified using the Qiaquick PCR Purification kit (Qiagen, Mississauga, Ontario) and sequenced using Perkin Elmer

dye terminator and ABI automated sequencing. Sequences were aligned and compared to sequences obtained from the control DNA and sequence available in public databases to identify mutations.

#### Results and Discussion

Spatial and temporal expression studies of the *Snf2l* gene in mice and the purification of two human SNF2L-containing complexes have both suggested that the SNF2L protein may have an important role in neurodevelopment and that the *SNF2L* gene is a strong XLMR candidate gene [17-19]. *In silico* analysis demonstrated that the *SNF2L* gene (NM\_003069) is highly conserved between mouse and human with a common intron/exon pattern containing 25 exons spanning ~77 kb along the X chromosome within Xq25 (Figure 1A and data not shown). However, the human cDNA and predicted protein sequences showed several significant discrepancies to the mouse *Snf2l* sequence (NM\_053123) that required characterization, prior to mutation studies [16,17]. Indeed, we previously reported the presence of a human *SNF2L* variant (SNF2L+13) containing a non-conserved in-frame exon within the SNF2 catalytic domain that abolishes chromatin remodeling activity [25]. In addition, Okabe et al. reported two human cDNA clones with disparate 5' ends [16]. We will refer to these two clones as *SNF2LA* and *SNF2LB*, respectively. *SNF2LB* aligns with the start of the murine cDNA sequence and corresponds to a transcript that would initiate within exon 1 of the human genomic sequence (Figure 1B). The shorter *SNF2LA* isoform results from transcription that initiates within exon 2. The corresponding proteins differ in size at the NH<sub>2</sub>-terminus by 78 amino acids with *SNF2LB* corresponding to the published murine sequence (Figure 1B). The *SNF2LA* isoform was not present in mice suggesting that it may be unique to humans. Using RT-PCR, we detected the corresponding transcripts for both 5' variants in human fetal brain and multiple human neuronal cell lines (Figure 1C).

In addition to the variation at the amino-terminus, the human and mouse amino acid sequences also differed at their carboxyl-terminus following Blast tool analysis. The last seven amino acids of the human sequence were not present in the mouse SNF2L protein sequence, but instead were replaced by 23 unique residues (Figure 2A). RT-PCR analysis demonstrated that both 3'-end variants could be detected in a variety of human cell lines, tissues and specific brain regions with the NLS-containing isoform representing the predominant species (Figure 2B). Sequencing demonstrated that the two transcripts are generated by alternative splicing of exons 24 and 25. Inclusion of exons 24 and 25 result in a shorter peptide due to a stop codon located at the start of exon 25. We called this variant SNF2LANLS. Alternative use of splice sites within exons 24 and 25 removes 100 bp and generates a transcript that

**Figure 1**

Below is a schematic diagram of the *SNF2L* transcript showing the ORF (open box) and the location of the motifs that comprise the SNF2 domain (blue boxes) and the SANT domains (red boxes). **B.** The 5' variants *SNF2LA* and *SNF2LB* provide alternative initiation codons and encode two forms of *SNF2L* with different amino-termini. They are shown aligned to the mouse *Snf2l* sequence. The *SNF2LB* transcript encodes a protein with an amino-terminus similar in length and amino acid composition to the murine *Snf2l* protein. **C.** RT-PCR analysis showing that both transcript variants are present in human cell lines and fetal brain tissue examined. The helicase I/IIa domain served as control amplification. Lane 1, 293 cells; lane 2, SH-SY5Y cells; lane 3, NT2 cells; lane 4, hNT neurons; and lane 5, human fetal brain. M, molecular weight marker.

**Figure 2**  
**Alternative splicing of exons 24 and 25 generates nuclear and cytoplasmic isoforms of SNF2L.** Alternative splicing of the *SNF2L* gene at the 3' end generates a transcript containing either the full sequence of exons 24 and 25, which encodes a shorter form of SNF2L without a nuclear localization signal (SNF2LΔNLS), or a transcript lacking 100 bp that encodes for a larger protein isoform (SNF2L) with an NLS (underlined). **B.** RT-PCR analysis demonstrated that both 3' variants are present in most cells and tissues examined, while the NLS isoform is predominant. M, marker; -D, no DNA template; -RT, no reverse transcriptase. Lanes 1–5, human cell lines and fetal brain sample as follows: 1, 293-HEK cells; 2, SH-SY5Y cells; 3, NT2 cells; 4, hNT neurons; 5, human fetal brain. Lanes 6–13, human brain regions including: 6, amygdala; 7, basal ganglia; 8, caudate nucleus; 9, cerebellum; 10, frontal cortex; 11, hippocampus; 12, pons; 13, thalamus. Lanes 14–20, human tissue samples including: 14, heart; 15, kidney; 16, liver; 17, ovary; 18, placenta; 19, skeletal muscle; and 20, testes. **C.** Indirect immunofluorescence imaging of 293 HEK cells transfected with FLAG-epitope tagged SNF2LΔNLS and SNF2L were stained with anti-flag antibody (green) or DAPI (blue). Note that SNF2LΔNLS encodes a protein that is localized exclusively in the cytoplasm while SNF2L is expressed only in the nucleus (arrows point to nuclei of transfected cells).

contains an additional 23 amino acids similar to the reported mouse protein (and herein called SNF2L). More importantly, we used the PredictNLS program [26] to determine that this alternatively spliced region contained a putative NLS sequence. To verify the importance of the NLS *in vivo*, we transiently transfected 293 HEK cells with FLAG-epitope tagged SNF2L or SNF2LΔNLS and detected the expressed protein by indirect immunofluorescence. As

shown in Figure 2C, SNF2LΔNLS localized exclusively in the cytoplasm whereas SNF2L was present in the nucleus.

The *SNF2L* gene undergoes alternative splicing at multiple sites to generate a wide number of different isoforms. Some of these isoforms will affect the activity of the protein. For example, the inclusion of exon 13 abolishes the chromatin remodeling activity [25], and the altered splic-

**Table 1: Mutation analysis of 12 families linked to Xq25 revealed 3 SNPs**

Location of SNP	SNP	Family	% of control sample with SNP (n = 100)	SNP Heterozygosity (SNP Database No.)
Exon 1 – 5'UTR 29 bp 5' of AUG	CTTGTCCC CTTATCCC	F93-04	13%	ND
Intron 13 48 bp 5' of exon14	CAACAGTA CAATAGTA	K8895	15%	0.359 (rs2274093)
Intron 18 74 bp 3' of exon18	CAGATTTAC CAGATTTIC	24981	0%	0.093 (rs3736692)

ing within exons 24/25 removes the NLS resulting in cytoplasmic localization. In the latter case, the SNF2L $\Delta$ NLS variant was detected in most tissues examined, suggesting that the cytoplasmic isoform of SNF2L may fulfill an alternative role to the chromatin remodeling function of the nuclear isoforms. Alternatively, it could represent a SNF2L dominant negative protein that sequesters other components of the chromatin remodeling complex in the cytoplasm. As such, it will be important to further explore the function of these novel SNF2L isoforms to determine their specific roles, similar to work done with the SNF2L+13 variant. Indeed, with splicing occurring at the 5'-end of the gene (isoforms SNF2LA and B), the 3'-end of the gene (NLS or  $\Delta$ NLS) and encompassing exon 13 (+exon 13 or -exon 13) there are 8 possible isoforms of the SNF2L protein that can impinge on the function/activity of the protein.

We have demonstrated that expression of the murine *Snf2l* gene increases during development in a manner that is coincident with neuronal maturation and synapse formation [17]. This expression profile is most prevalent in the hippocampus, dentate gyrus and the cerebellum and expression within these structures is maintained in the adult mouse [17]. Given that the hippocampus and dentate gyrus have been implicated in learning and memory, and that mutations in genes involved in chromatin remodeling or modification cause mental retardation, it prompted us to examine the human *SNF2L* gene as a candidate XLMR gene. DNA samples from 12 individuals affected with XLMR and previously mapped to a region encompassing the *SNF2L* gene were used for direct sequencing analysis. We sequenced each of the 25 exons and flanking intron sequences of the *SNF2L* gene and identified 3 different single nucleotide polymorphisms (SNPs), all located in untranslated sequences (Table 1). Screening of 100 unaffected individuals demonstrated that the SNP in the 5' UTR of exon 1 and the polymorphism in intron 13 (rs2274093) had frequencies of 13% and 15% respectively, in our control population. Conversely, the SNP in intron 18 was not found in our control DNA samples, but screening of the SNP database identified it as a polymorphism with a heterozygosity frequency of 0.093 (rs3736692). Overall, the SNP database contains 195 entries for the *SNF2L* gene including 5 in the coding region (exons 1, 10, 16, 17, and 20). The SNP within exon

20 is reported to have a heterozygosity value of 0.026 and would result in an Ala to Gly substitution. While we did not find this change in any of our families, future analysis of this gene should be wary of this polymorphism.

Despite the absence of mutations in these families, SNF2L remains a logical candidate for XLMR localized to Xq25-26 because of (a) its similarity to *ATRX*, a SNF2-domain containing protein mutated in several XLMR disorders; (b) its high expression in the brain including areas important for learning and development; and (c) its ability to induce neuroblastoma cells to undergo differentiation when ectopically expressed [17,18]. In addition, SNF2L has been shown to regulate the engrailed genes, *En-1* and *En-2*, both of which are important for mid/hind-brain development [27,28], the latter of which has been associated with autism in genetic linkage studies [29-31]. Given these criteria and the small sample size available for mutation analysis, other syndromes should be considered for screening, including the Shashi XLMR syndrome [32,33] and a family with syndromal XLMR and late-onset testicular failure (Cillier syndrome) [34] that both map to Xq26. In addition, there are 3 other syndromes (Wilson/MRXS12, Gustavson, and CMTX4/Cowchock-Fishbeck) and 8 MRX families (MRX 27, 35, 42, 62, 70, 71, 75, and 82) that map to this region that should also be considered in future screening endeavors [35]. The generation of a transgenic mouse ablated for the *Snf2l* gene should provide valuable phenotypic insight for its potential involvement in specific XLMR disorders. Together, the analysis of additional samples and the characterization of transgenic mice should define whether the SNF2L gene is a cause of mental retardation.

## Conclusion

We have shown that there are multiple SNF2L isoforms that result from alternative splicing of the gene. How these different isoforms are spatially and temporally regulated and defining their specific role during neural development remains to be established. In our collection of 12 patients with XLMR linked to Xq25-26, we did not identify any mutations within the coding region. However, we cannot exclude intronic mutations (outside of the consensus splice sites) that would affect alternative splicing and hence the expression levels of the different isoforms. Similarly, we cannot exclude mutations in regulatory regions

in the 12 families screened for mutations in this gene. Alternatively, our failure to identify mutations may arise from (1) the small sample size which may have prevented us from ascertaining a family with a mutation in this gene, or (2) the possibility that mutations in SNF2L could cause a more severe phenotype that may be lethal in males. Indeed, SNF2L remains a candidate XLMR gene for Xq25-26 linked XLMR families including the Shashi syndrome as well as in sporadic mental retardation cases.

### Competing interests

The author(s) declare that they have no competing interests.

### Authors' contributions

MAL identified the various SNF2L isoforms, generated the preliminary RT-PCR data and performed the immunofluorescence experiments. MAMT extended the RT-PCR experiments to include the multiple human tissues and brain regions. PL and DV performed the sequence analysis of the XLMR patients. AD prepared the initial figures and wrote the first draft of the manuscript. DJP designed the study, participated in its execution and coordination and wrote the final manuscript. All authors have read and approved the final manuscript.

### Acknowledgements

The authors would like to thank Drs. Allanson, Hamel, Schwartz, and Van Bokhoven for their generosity in providing patient DNA samples. This work was supported by grants from the Ontario Mental Health Foundation and the Neuromuscular Research Partnership (JNM-78384), an initiative of the ALS Society of Canada, Muscular Dystrophy Canada, and the Canadian Institutes of Health Research.

## **APPENDIX C**

### **SCO-ping Out the Mechanisms Underlying the Etiology of Hydrocephalus**

## **Purpose**

To review the literature concerning the contributions of the subcommissural organ (SCO) and the ventricular ependyma of the brain towards the onset of congenital hydrocephaly in both humans and animal models.

## **Submission Information**

Submitted: December 2008

Accepted: February 2009

Published: 1 April 2009

Reprinted from “**Physiology, Huh, M.S., Todd M.A.M., and Picketts D.J., SCO-ping out the mechanisms underlying the etiology of hydrocephalus, 2009, Volume 24, pp 117-126,**” in accordance with the copyright (2009) permission policies of The American Physiological Society.

## **Contribution of Co-Authors**

Matthew A.M. Todd contributed Figure 2 and Table 1 and wrote the following sections: “Signal Transduction and the Regulation of SCO Secretion,” “The Contribution of the Ventricular Cilia to CSF Homeostasis,” and “Cell Adhesion Molecules and Hydrocephalus.”

Michael S. Huh contributed Figure 1 and wrote the “Loss of Developmental Factors Impairs SCO Formation and Function” section. The remaining sections were co-written by all authors. Matthew A.M. Todd and Michael S. Huh contributed equally to the writing of this manuscript, while David J. Picketts edited the manuscript.

## SCO-ping Out the Mechanisms Underlying the Etiology of Hydrocephalus

The heterogeneous nature of congenital hydrocephalus has hampered our understanding of the molecular basis of this common clinical problem. However, disease gene identification and characterization of multiple transgenic mouse models has highlighted the importance of the subcommissural organ (SCO) and the ventricular ependymal (vel) cells. Here, we review how altered development and function of the SCO and vel cells contributes to hydrocephalus.

The cerebral spinal fluid (CSF) flow tract is a vital lifeline for supplying the brain with essential nutrients and growth factors throughout development and into adulthood. At the same time, the brain exercises constant control to ensure that the flow of CSF is homeostatic. CSF is secreted by the choroid plexus and moves rostrocaudally through the ventricles and into the subarachnoid space before being drained into the venous circulation (80). Failures within this cerebral irrigation network can lead to a buildup of CSF in the ventricular cavities of the brain, a condition known as hydrocephaly, which is fatal without surgical intervention. Hydrocephalus can result from an overproduction of CSF by the choroid plexus, failure to drain the CSF at the subarachnoid space, and the blockage of CSF flow through the narrow Sylvian aqueduct, which is situated between the third and fourth ventricles. Indeed, stenosis of the Sylvian aqueduct is considered the primary cause of congenital hydrocephalus, which is quite frequent, occurring with an incidence of 0.1–0.3% of live births (80). The causes for this disease are quite heterogeneous and have been linked to a number of genetic mutations, both autosomal and X-linked (112). What is intriguing, though, is that many of these mutations impinge on the development or function of the subcommissural organ (SCO) and the ventricular ependymal (vel) cells that collectively facilitate the flow of CSF through the confining canals of the ventricular system (Table 1).

The goal of this review is to summarize the molecular mechanisms that cause 1) the SCO to be absent or disorganized, 2) an inability of the SCO to properly secrete glycoproteins, 3) primary ciliary dyskinesia (PCD) of the ependymal cells, and 4) denudation of the neuroependyma. Although it should be noted that not all SCO/vel defects have been proven to precede the onset of hydrocephaly, indeed it is the aberrant execution of these diverse molecular pathways that can lead to stenosis of the aqueduct and contribute to communicating or noncommunicating hydrocephalus.

### Loss of Developmental Factors Impairs SCO Formation and Function

The SCO is a small secretory gland positioned in the dorsal caudal aspect of the third ventricle underneath the posterior commissure. The SCO is derived from the neuroepithelial cells that line the lumen of the dorsal-caudal aspect of the diencephalon. This anatomical region is also described as the prosomere 1 (P1), demarcated by the pineal gland and the mesencephalon. The primitive epithelial progenitors of the presumptive SCO are driven toward a specialized secretory ependymal cell fate in response to the inductive Wnt and Bmp signals emanating from the roof plate of the dimesencephalon boundary (FIGURE 1A). Indeed, the roof plate acts as an important organizing center for the secretion of these morphogens that are crucial for establishing the dorsal-lateral identity along the central nervous system (CNS) (31, 58, 59). Although malformation of the SCO during gestation leads to ventricular dilation and aqueductal stenosis before birth (FIGURE 1, B AND C) (32, 80), the involvement of specific factors has been slowly elucidated over the past decade through the analysis of mutant mouse models.

One such protein is *Msx1*, a critical factor involved in dorsal neural patterning (3, 84). *Msx1* along with *Msx2* and *Msx3* form a family of homeodomain transcriptional repressors (18, 96, 111). The earliest expression of *Msx1* is observed at the neural fold stage, along the boundary of the neural plate (17, 38). Upon closure of the neural tube, *Msx1* is prominently expressed along the entire length of the dorsal midline of the neural tube. *Msx1* is also expressed in the SCO, choroid plexus (CP), and the habenula in the third ventricle (84). Bach et al. clearly demonstrated that homozygous mutants for *Msx1* were unable to sustain Wnt1 and Bmp6 expression in the dorsal midline of P1, and histological analysis demonstrated the absence of a SCO and a poorly organized posterior commissure (3, 84). Loss of morphogen induction in P1 consequently downregulated cell fate markers such

as Pax6, Pax7, and Lim1, whereas the P2 marker Gbx2 remained unaffected. The *Msx1* mutant mice developed hydrocephaly, and the interactions of *Msx1* with Wnt1 and Pax6 are corroborated by similar hydrocephalic phenotypes in *Wnt1<sup>sw/sw</sup>* and *Pax6<sup>sey/sey</sup>* mice (27, 60).

It is also possible that *Msx1* may regulate genes that maintain homeostasis in the mature SCO ependymal cells. *Msx1* is already known to influence a diverse set of gene expression programs during neuronal development (85). Moreover, the residual ependymal cells of the SCO were not immunoreactive with anti-Reissner's fiber serum (AFRU), suggesting the absence of glycoprotein secretion (84). Although multiple roles are suggestive, additional studies such as temporal inactivation of *Msx1* will be required to determine whether *Msx1* directly regulates the expression of secreted glycoproteins and cell adhesion molecules in secretory ependymal cells. *Msx1<sup>+/-</sup>* mice are viable, but one-third of them develop hydrocephaly, likely due to the reduction in SCO size (29).

The regulatory factor X (Rfx) family represents a second class of transcription factors expressed in the dorsal neural tube, and two family members, Rfx3 and Rfx4\_v3, are important for the development of the SCO (2, 11). The Rfx proteins are winged-helix transcription

factors that form either homo- or heterodimers to regulate target genes (45, 71, 86) and are known to direct the formation of ciliated cell types in metazoans (1, 12, 26, 35, 52, 97, 101). Both *Rfx3* and *Rfx4\_v3* transcripts are expressed embryonically in the dorsal aspect of the neural tube and are highly expressed in the ependymal cells of the SCO in the embryo and adult (2, 11). Additionally, Rfx3 expression is prominent in the ependymal cells of the CP and is sustained in all ciliated ependymal cells from the moment of birth to adulthood (2). Not surprisingly, *Rfx3<sup>-/-</sup>* mice that come to term invariably develop communicating hydrocephaly (2). In the *Rfx4\_v3* mice, congenital non-communicating hydrocephaly was observed in the heterozygous condition (11). The agenesis of the SCO was a common feature found in both *Rfx3<sup>-/-</sup>* and *Rfx4\_v3<sup>+/-</sup>* mice (2, 11). The absence of a functional SCO was ascertained by the degree of immunoreactivity using anti-SCO-spondin (*Rfx3<sup>-/-</sup>*) and anti-RF (*Rfx4\_v3<sup>+/-</sup>*) in the presumptive SCO region. In both studies, the degree of immunoreactivity was significantly reduced. Although both mouse knockout models resulted in the absence of a functional SCO, an intriguing observation was reported in the case of the Rfx3 phenotype. The *Rfx3<sup>-/-</sup>* mice appeared to have an

\*Unless otherwise stated, all mutations are inactivating.

overall dysfunction in the development of the ciliated ependymal cells. More specifically, the CP was poorly formed or improperly differentiated, with a lack of cilia present on the apical surface. Furthermore, the cell adhesion properties of the CP ependymal cells were compromised since the interdigitations between cells were poorly formed and the basal membrane was not apposed to the basal lamina. This apparent lack of differentiation was also observed in the SCO where its ependymal cells were more cuboidal with many cilia, appearing similar to the ependyma lining the ventricles (2).

In the case of the *Rfx4\_v3* studies, homozygous knockouts of *Rfx4\_v3* strongly suggest its role as a critical mediator of an earlier dorsal midline patterning decision. *Rfx4\_v3*<sup>-/-</sup> mice were embryonic lethal due to catastrophic midline defects. *Rfx4\_v3*<sup>-/-</sup> telencephalon at E12.5 were characterized by hypoplasia of the dorsal midline and adjacent cerebral cortex. The dorsal midline defect was also evident due to the down regulation of *Wnt7a* and *Wnt7b* in the cortical hem, a midline structure that normally produces these transcripts (11). A recent microarray experiment identified components of the Wnt, Bmp, and retinoic acid signaling pathways to be potential targets of *Rfx4\_v3* in E10.5 brains (110).

From the studies described above, tight regulation along the dorsal midline through Wnt and Bmp signal-

ing pathways is an important regulatory mechanism for the proper development of the differentiated ependymal cells of the SCO and for preventing the onset of hydrocephalus. Indeed, this is also noted in mice that ectopically express *Engrailed-1* (*En-1*), a transcription factor that is important for establishment of the mid-hindbrain boundary, since these animals were presented with hydrocephaly and SCO agenesis in the P1 domain (60). Similarly, a recent report by Dietrich et al. produced a mouse model linking the Huntington's disease gene (*Hdh*) to congenital hydrocephaly (24). In this study, a mid- to hindbrain-specific inactivation of *Hdh* was generated by crossing *Hdh*<sup>lox</sup> mice with animals that express Cre under the control of a *Wnt1* regulatory element. The *Wnt1-Cre:Hdh*<sup>lox</sup> mice came to term but displayed reduced growth and progressive wasting due to the build up of excessive CSF, expansion of the ventricles, and the loss of cortical tissue. Histology revealed expansion of the lateral ventricles by E17.5, indicating the congenital nature of the hydrocephaly. Despite the complete absence of huntingtin (*htt*) in the mutant CP, no gross structural defects were observed using immunohistochemistry for a variety of markers (24). The effect of *htt* loss was more overt in the mutant SCO. Mutant SCO was ~40% the size of the controls. Serial coronal

**FIGURE 1. Genetic determinants of congenital hydrocephaly and subcommissural organ agenesis**

A: molecular regulation of dorsal midline patterning in prosomere1 (P1) in an E10.5 mouse embryo. A coronal section of the neural tube through the di-mesencephalic boundary depicts the roof plate in yellow and the underlying dorsal primitive neuroepithelium in red that gives rise to the subcommissural organ (SCO). *Msx1* expression in the midline activates the expression of Wnts and Bmps. Wnt and Bmp signaling from the roof plate induces the expression of *Pax6* and *Lim1* in a dorsal-lateral gradient. *Rfx3* and *Rfx4\_v3* are also expressed at this stage in the dorsal-medial region. B: sagittal section of a normal E18.5 mouse brain depicting the cerebral spinal fluid (CSF) flow. The CSF flows unimpeded, circulating from the lateral (LV) and third ventricles (III-V) and in through the Sylvian aqueduct (SA). The SCO (red) is positioned immediately anteriorly to SA and is believed to facilitate the flow of the CSF by the secretion of glycoproteins and the formation of Reissner's fibers (not represented in this figure). Other structures in this panel are cortical plate (CoP), choroid plexus (CP), fourth ventricle (IV-V), posterior commissure (PC), and cerebellum (Ce). C: sagittal section depicting a hydrocephalic E18.5 mouse brain. Mutations in genes that regulate the tightly controlled patterning in the dorsal midline of P1 lead to SCO malformation and congenital hydrocephaly. *Wnt1*, *Msx1*, *Rfx3*, *Rfx4\_v3*, *Pax6*, and *Engrailed* have been demonstrated to be critical players in this process. Misregulation of these genes frequently leads to agenesis of the SCO (dotted area) and the stenosis of the SA. The closure of the SA causes an accumulation of the CSF resulting in dilatation of the III-V and LV. The enlargement of the ventricles results in a secondary loss of cortical tissue and a characteristic doming of the cortex.

sections revealed that only the rostral portion of the SCO appeared properly differentiated as detected by SCO-spondin staining. Moreover, caudal to the SCO domain, ectopic SCO-spondin expression was detected in the ependymal lining of the Sylvian aqueduct (24). Further characterization of these mice is needed to determine whether the defect lies in inappropriate secretion of glycoproteins from the SCO or altered function of the vel cells lining the aqueduct. Nonetheless, these findings suggest that *htt* has a role in regulating the function of specialized ependymal cells.

Taken together, the proper development of the SCO is essential for CSF circulation through the narrow Sylvian aqueduct, and other factors that regulate dorsal patterning at or near the mid-hindbrain boundary are potential candidates for genetic causes of congenital hydrocephaly. In this regard, a protein like *Snf2l*, which modulates chromatin structure and expression of *En-1*, may potentially have dire consequences for hydrocephaly (8). Although we are only beginning to unravel the multitude of factors that control the cell fate decisions in this region and the

terminal differentiation of the specialized cells of the SCO and vel, it is apparent that there is extreme heterogeneity underlying hydrocephalus. It should also be mentioned that other transcription factors, such as *Otx2*, are known to be associated with hydrocephalus when inactivated in mice; however, such a phenotype is unlikely to be SCO-specific and likely constitutes a more general defect in brain development (62). Although development seems to have a significant role in the etiology of hydrocephalus, aberrant function of the SCO and vel cells has also been implicated in this disease.

### Signal Transduction and the Regulation of SCO Secretion

The primary function of the SCO is to secrete high molecular weight glycoproteins that facilitate CSF flow and, in rodents, contribute to the formation of Reissner's fiber (RF), which extends along the length of the CSF tract to the ampulla caudalis (89). The major secreted glycoprotein and constituent of RF is SCO-spondin, a highly conserved protein containing

**FIGURE 2. Molecular pathways in ependymal cells implicated in congenital hydrocephalus**

Schematic representation of a SCO/vel ependymal cell highlighting the numerous molecular pathways underlying congenital hydrocephalus. Neuropeptides (Pacap, serotonin) induce cell signaling pathways that alter target gene regulation, presumably genes encoding secreted glycoproteins and proteins involved in ciliary function. The *Socs7* protein is a regulator of the *Jak/Stat* signaling pathway. Ablation of several transcription factors (*Msx1*, *Rfx3*, *Rfx4\_v3*) alters the terminal differentiation or cell fate of the ependymal cells. Numerous proteins (*Mdnah5*, *Hydin*, *Pcdp1*, *Spag6*, *Polaris*) and transcriptional regulators (*Foxj1/Hfh-4*, *Pol λ*) involved in the formation and function of cilia are implicated in hydrocephalus and are shown at the top of the diagram. The  $\alpha$ -Snap protein is involved in regulating the transport of cell adhesion molecules (*NmhclIb*, *cadherin*) to the apical cell surface and presumably also for proper glycoprotein secretion.

many protein-protein interaction domains that have fostered its numerous putative functions, including axonal pathfinding, promoting neuronal survival and neurite extension, and a detoxifying activity by removing monoamines from the CSF (67, 68). Regardless of its precise function, alterations in SCO secretions have been shown to precede diagnoses of hydrocephalus (99). Although transcription factors that promote terminal differentiation are important for regulating the expression of secreted proteins (e.g., *Msx1*) from the SCO, increasing evidence implicates signal transduction mechanisms in the processes regulating SCO secretion as a cause of hydrocephalus (FIGURE 2). The importance of signaling pathways downstream of G-protein-coupled receptors (GPCR) (73) in particular may modulate SCO glycoprotein secretion through the induction of transcriptional regulators, such as CREB, and perhaps also through the induction of intracellular calcium levels (10, 50, 74, 81, 94, 95). Recently developed hydrocephalic transgenic mouse models (*Pac1*, *Ro1*) seem to indicate that GPCR concentrations are rigidly controlled (50, 100).

The PACAP type I (*Pac1*) receptor is one example of a GPCR that contributes to hydrocephaly (50). Murine *Pac1* is highly expressed in neural progenitor cells, and transgenic *Pac1* was also found to be highly expressed in the differentiated SCO and ventricular ependyma (50, 106). Pituitary adenylate cyclase-activating polypeptide (PACAP) is the primary *Pac1* ligand, and its interactions with *Pac1* have been shown to activate or inhibit a variety of downstream signaling pathways, including PKA, PKC, MAPK, RhoA, and  $IP_3$  (FIGURE 2) (66). Transgenic mice that overexpressed *Pac1* developed communicating hydrocephalus with an enlarged aqueduct, which was associated with apoptosis-related SCO agenesis and shortened disorganized ventricular cilia (50). The mutant phenotype was correlated with an activation of both PKA and PKC signaling; however, the impact on SCO secretion was not assessed.

Neurotransmitting hormones are some of the most well characterized ligands of GPCRs, and the SCO is well innervated by serotonergic, GABAergic, dopaminergic, and noradrenergic fibers (42). Serotonin and GABA have also been previously characterized as regulators of SCO secretion; however, the molecular mechanisms have not been well explored (56, 70, 92). The most recent molecular studies concerning the effect of neurotransmitters on SCO secretion demonstrate a significant amount of serotonin and dopamine receptors on the apical surface of the mammalian SCO ependyma, implicating the CSF as the primary source of their respective ligands (87, 103). Although dopamine signaling did not have any significant effect on SCO secretion, serotonin signaling through the  $5HT_{2A}$  receptor, which primarily stimulates the phospholipase C (PLC) pathway, was shown to inhibit the transcription of SCO-spondin. To date, defects in serotonin signaling have not been identified

as a primary cause of hydrocephalus. However, a significant reduction in the rate of serotonin turnover has been observed in the CSF of human infants suffering from hydrocephalus (34), which may account for secondary defects in SCO secretion that could contribute to a worsening of the disease.

*“Recent molecular evidence in humans indicates that the direction of cell adhesion molecules to the proper surface is vital.”*

Abnormal cytokine and growth factor signaling pathways have also been linked with hydrocephaly (reviewed in Ref. 112). One study has shown that suppressor of cytokine signaling 7 (*Socs7*) mutant mice develop late-onset communicating hydrocephalus, where the only observable physiological abnormality is a disorganized SCO (48). Abnormalities in SCO secretion and RF formation were not examined. SOCS proteins are traditionally considered to suppress cytokine signaling by binding to JAK receptors to prevent STAT transduction into the nucleus (51). Although this may be the role of *Socs7* in SCO cells, the protein has also been implicated in several nontraditional transduction roles, including its binding to phosphorylated STATs (63), binding to other SOCS proteins (82), binding to the actin cytoskeleton through interactions with septins or vinexin (46, 49, 64), or contributing to the regulation of the actin cytoskeleton and cell cycle mechanisms by shuttling NCK to the nucleus (46, 49). At this time, the molecular significance of SOCS7 with respect to the SCO remains to be characterized.

Taken together, these studies highlight the possibility that constituents of the CSF feedback on the SCO to regulate glycoprotein production and/or secretion. Although disruptions in specific signaling pathways have not yet been proven to be a primary cause of hydrocephaly, it represents an exciting area for future studies that would provide an additional layer of complexity to our understanding of the causal mechanisms of congenital hydrocephalus and SCO function.

### The Contribution of Ventricular Cilia to CSF Homeostasis

The ventricular ependyma shares complementary functions with the SCO in regulating CSF homeostasis and preventing the onset of hydrocephalus (81). Besides the requirement for SCO glycoproteins and RF to prevent stenosis of the Sylvian aqueduct, a unidirectional laminar flow of CSF generated by the ciliated ependyma is essential (41).

Hydrocephalus in humans arises in several ciliopathies, disorders that have been attributed to defects in cilia structure and function (4, 30, 40, 109). In the ventricular ependyma, the ciliary core, or axoneme, consists of an arrangement of a central pair of microtubules surrounded by nine peripheral microtubule doublets. Radial spokes project from the central pair and interact with the peripheral doublets, presumably to regulate interactions with dyneins, which are motor proteins that are responsible for generating ciliary beat (91).

Mouse axonemal dynein heavy chain (*Mdnah5*) was identified as a protein that is important for laminar CSF flow through the Sylvian aqueduct (41). *Mdnah5*-null mice have immotile cilia due to the absence of outer dynein arms in the axoneme (39). Its human counterpart, DNAH5, has been linked to outer dynein arm defects that lead to PCD, although only a small percentage of human patients carrying *DNAH5* mutations develop hydrocephalus (37, 75).

The molecular characterization of the hydrocephalus-3 (*hy3*) mouse, a commonly studied model of hydrocephalus, resulted in the identification of the *Hydin* gene (22). *Hydin* is a putative microtubule binding protein (83) required for the formation of a specific projection emanating from one of the central pair microtubules (23, 53, 54). Lechtreck et al. believe that *Hydin* is a dynein adaptor that is required to regulate the transition between the ciliary effective and recovery strokes (53, 54). This proposal is consistent with observations that the ependymal cilia of *hy3* mice have difficulty bending, leading to ciliary beats with reduced frequency and impaired synchronicity (53). At the same time, these cilia do not appear to have any structural defects other than the lack of this single central pair projection. The authors note that the phenotype is similar to that of PCD patients who suffer defects in the inner dynein arms or the radial spokes (21, 53).

Sperm-associated antigen 6 (*Spag6*) is another factor that associates with a specific central pair projection and, along with its interacting partners *Spag16* and *Spag17*, is required for ciliary motility (93, 113–115). Like *Hydin*, *Spag6*<sup>-/-</sup> mutants suffer from hydrocephalus. The extent of the phenotype is made more severe when both *Spag6* and *Spag16* are knocked out, although *Spag16*<sup>-/-</sup> mice are not hydrocephalic (116). The ultrastructure of the ependymal cells in these animals appears normal, suggesting a molecular pathology that is similar to *hy3* mice. Moreover, *Spag6* has been described as a candidate gene for hydrocephalus in H-Tx rats, another commonly studied hydrocephalus model (43).

PCD protein 1 (*Pcdp1*) is another putative central pair-binding protein that, when ablated in mice, results in hydrocephalus (55). As with *hy3* and *Spag6*<sup>-/-</sup> mice, the tracheal cilia of the *Pcdp1*<sup>-/-</sup> mice

have a reduced beat frequency but do not display any obvious ultrastructural axonemal defects. The ultrastructure and ciliary beat frequency of ependymal cilia were not reported, although *Pcdp1* was identified throughout the cilia of human brain ependymal cells.

In the *Tg737<sup>orpk</sup>* mouse (57), mutations in the intraflagellar transport protein (91) *Polaris/Ift188* also led to hydrocephalus. Although ependymal cilia are shorter, disorganized, and beat asynchronously, the primary cause of hydrocephaly in these mice appears to be the regulation of intracellular and secretory mechanisms of the choroid plexus in response to the defects in the structure and function of its cilia (5, 6). IFT components appear to be well conserved and many await characterization, so it remains to be seen whether mutations in additional IFT factors also result in hydrocephalus.

Defects in the expression of transcriptional regulators that mediate ciliogenesis can also lead to hydrocephalus. For example, *Foxj1/Hfh-4* is an important transcriptional activator of numerous genes required for the development of motile cilia and has been associated with left-right asymmetry developmental defects and associated hydrocephaly (13, 20, 108). Similarly, mice that lack DNA polymerase  $\lambda$  (*Pol*  $\lambda$ ) also develop hydrocephalus (47). Although *Pol*  $\lambda$  is generally considered to be a DNA repair enzyme, it is required for the proper expression of the axonemal inner dynein arms whose dysfunction likely contributes to the hydrocephaly in these animals (33).

In this section, we have highlighted recent advances characterizing defects in ciliary structure and function that result in hydrocephalus. It is likely that additional proteins that interact with or comprise the cilia ultrastructure are potential candidates to be implicated in hydrocephalus in the near future.

## Cell Adhesion Molecules and Hydrocephalus

The ependymal cells of the SCO possess tight junctions and zonulae adherens, which contribute to the formation of a blood-brain barrier between the vasculature and the ventricular cavities (89). Adding to the complexity of its functions is accumulating evidence that the SCO is able to act as a mechanosensor, altering the way it secretes glycoproteins in response to signals sent from circulating blood, as shown in hypertensive rats (65). In this regard, it is intriguing that hypertension was also observed in both *Pac1*-null and -overexpressing transgenic mice (50). Regardless, the presence of such a blood-brain barrier necessitates a functional complement of cell adhesion molecules.

Recent molecular evidence in humans indicates that the direction of cell adhesion molecules to the proper surface is vital. Mutations in the vesicular

transport proteins FILAMIN A and ARFGEF2 lead to periventricular heterotopia, which is associated with a reduction in cell adhesion and a loss of the neuroependyma, and is sometimes accompanied by hydrocephalus (28, 77, 98). In the hydrocephalus with hop gait (*hyh*) mouse, hydrocephalus is accompanied by a denudation of the ependymal cell layer (14, 79, 105). Ependymal denudation of the SCO has been identified in cases of human hydrocephaly (25).

A mutation in the soluble NSF attachment protein  $\alpha$  ( $\alpha$ -Snap), which directs secretory vesicles to the apical cell surface, was found to be responsible for the *hyh* phenotype (19, 36).  $\alpha$ -Snap is known to direct cell adhesion molecules, such as E-cadherin and  $\beta$ -catenin, to the apical surface of neural progenitors (9, 19, 76). In vel cells, non-muscle myosin II-B heavy chain (Nmhc-IIb) forms a mesh-like structure with N-cadherin and  $\beta$ -catenin at the apical surface, thus it is possible that  $\alpha$ -Snap is involved with the localization of one or more of these structural components (FIGURE 2) (61). Similar to the *hyh* phenotype, the loss of Nmhc-IIb results in a loss of integrity in the neuroepithelium, leading to hydrocephalus and defects in neuronal cell migration (61, 104). This phenotype can be somewhat rescued by replacing the expression of Nmhc-IIb with Nmhc-IIa (7).

### Mouse-Human SCO Differences and the Relationship to the Human Condition

CNS patterning is a highly conserved process underpinned by fundamental molecular pathways and interactions in all vertebrates. Moreover, select classes of transcription factors such as the bHLH, homeobox, and paired box family are key regulators of CNS development in metazoans. Taken together, it suggests that mouse models represent a powerful system in which to understand the etiology of hydrocephaly in humans. Indeed, the presence of the SCO/vel in even the earliest of vertebrates suggests a high degree of conservation in the expression of factors that regulate the development and functionality of these tissues, and one might predict that most of the factors identified in mice (e.g. Rfx3, Rfx4\_v3) would be prime candidates to cause human hydrocephaly. Unfortunately, studies that implicate the SCO-related developmental transcriptional regulators as a direct cause for human hydrocephaly have not been forthcoming as of yet.

Despite the similarities in SCO development and function, there are controversies that surface when drawing parallels between human and mouse that arise from SCO morphological differences. Unlike most other vertebrates, in which the SCO remains fully differentiated and active throughout adulthood, the human SCO reaches its functional peak of glycoprotein secretion during embryonic development (88). During later embryonic stages and postnatally, the SCO begins to regress to the point where, by late child-

hood, secretion is limited to only a few remaining islets. Additionally, the glycoproteins secreted by the human SCO do not aggregate into RF nor do they immunoreact to antibodies raised against RF-glycoproteins in other mammals, indicative of some differences in the secretory role of the human SCO vs. that of the mouse (88). Indeed a pessimist would argue that these interspecies differences supersede the benefits of studying hydrocephaly in models where the SCO is implicated. Although the species-specific roles of the SCO present challenges to the field, the adult vel still contributes to hydrocephalus in both species. In this regard, shared vel signaling pathways or factors involved in ciliary structure and function should allow for meaningful comparisons to be made; however, these comparisons are rare and tenuous at best. For example, the gene for the human PAC1 receptor is located at 7p15. Although a link could be made to communicating hydrocephalus, only a single patient with a duplication of this region has been described (69). The gene for its ligand, PACAP, is located at 18p11, and congenital hydrocephalus is one of the symptoms experienced by patients with tetrasomy 18p (102). Similarly, HYDIN, located at 16q22, is a candidate for one case of human hydrocephaly (16). A large-scale genetic screen has also recently revealed that mutations in a human-specific HYDIN paralog located at 1q21 may contribute to a number of behavioral and congenital brain disorders, although hydrocephalus was present in only a small number of these patients (15). Additional comparisons between human and mouse are summarized in a recent review of the genetics of human hydrocephaly (112).

Although we have highlighted a role for many factors in the etiology of hydrocephaly in the mouse, human studies identifying causative genes are lagging far behind. One reason for this delay may evolve from the general nature of hydrocephaly itself. It is a very heterogeneous disorder and without the availability of large families for genetic studies it is difficult to group patients together for successful linkage analyses. Another consideration is that many of the animal studies describe the ablation of specific genes that may be embryonic or early postnatal lethal in humans. Alternatively, viable human mutations in the gene may result in subtler phenotypes with little or no penetrance of hydrocephaly. On the other hand, the identification of human genes should be studied in mice to further characterize the similarities and differences between the two species in disease development. In this regard, L1-CAM, an X-linked cell adhesion molecule important for neurite outgrowth, is the best characterized determinant of congenital human hydrocephaly, and mouse models have been shown to accurately recapitulate the human phenotype (44, 72, 90, 107). Overall, a combination of animal and human studies remains the best approach for disease gene identification.

## Concluding Remarks

Collectively, these studies demonstrate that defects in multiple aspects of SCO cell function are implicated in the development of congenital hydrocephalus. As such, the new frontier for SCO research is clearly toward a further understanding of the molecular mechanisms governing SCO development and function. The plethora of genetic mouse models available is phenomenal and should continue to be extremely valuable for researchers in this field and in the hunt for causes of human hydrocephaly.

Developmental studies will continue to elucidate the hierarchical transcription factor organization that dictates the stage-specific differentiation of these cells and underlies the critical points of functional regulation. Defining these pathways will present researchers with candidate disease genes and opportunities to augment differentiation of progenitors toward a SCO fate to generate cell culture models. Similarly, a complete understanding of the signaling mechanisms between the CSF and SCO/vel cells should identify ligands that could be administered to promote glycoprotein secretion and restore CSF homeostasis. Finally, the use of high throughput approaches will enhance the knowledge of the important protein-protein interactions. For example, proteomic approaches have been used in the initial characterization of the secreted glycoproteins from the SCO and, more generally, for delineating the ciliary proteome (78). Interestingly, this proteomic study identified more than 600 proteins, of which over 200 were conserved between humans and *Chlamydomonas*, including a surprising number of proteins involved in signal transduction mechanisms (78). All of these approaches will increase our knowledge of SCO function and help elucidate where similarities to human hydrocephaly exist, thereby facilitating the characterization of genetic causes of congenital hydrocephalus. ■

Chromatin compaction mediates progenitor to post-mitotic cell transitions and modulates gene expression programs, yet the mechanisms are poorly defined. *Snf2h* and *Snf2l* are ATP-dependent chromatin remodelling proteins that assemble, reposition and space nucleosomes, and are robustly expressed in the brain. Here we show that mice conditionally inactivated for *Snf2h* in neural progenitors have reduced levels of histone H1 and H2A variants that compromise chromatin fluidity and transcriptional programs within the developing cerebellum. Disorganized chromatin limits Purkinje and granule neuron progenitor expansion, resulting in abnormal post-natal foliation, while deregulated transcriptional programs contribute to altered neural maturation, motor dysfunction and death. However, mice survive to young adulthood, in part from *Snf2l* compensation that restores *Engrailed-1* expression. Similarly, Purkinje-specific *Snf2h* ablation affects chromatin ultrastructure and dendritic arborization, but alters cognitive skills rather than motor control. Our studies reveal that *Snf2h* controls chromatin organization and histone H1 dynamics for the establishment of gene expression programs underlying cerebellar morphogenesis and neural maturation.

The importance of epigenetic regulation to brain development is recognized by the increasing number of developmental disorders caused by mutations in genes that encode proteins that modify or remodel chromatin structure<sup>1</sup>. Nonetheless, discerning precise mechanisms has proven challenging since these proteins impact all nuclear processes from transcription and replication to higher-order chromatin compaction. Genome-wide epigenetic profiling experiments have supported the hypothesis that neurogenesis is accompanied by the transition of a highly dynamic chromatin environment within progenitor cells to a more restrictive epigenetic landscape that dictates gene expression programs specific to each lineage<sup>2,3</sup>. Chromatin restriction involves the expansion of repressive histone marks such as H3K9Me3 and H3K27Me3, increased DNA methylation and a reduction in the distribution of the histone variant H2A.Z within gene bodies slated for silencing<sup>4,5</sup>. Concomitant with these histone and DNA modifications, chromatin compaction also requires regular nucleosome spacing and the inclusion of the linker histone H1<sup>6,7</sup>.

The repositioning of nucleosomes is catalysed by evolutionarily conserved multiprotein chromatin remodelling complexes (CRCs) that include a SNF2-domain containing catalytic subunit related to the Swi2/Snf2 family<sup>8</sup>. One such class of ATP-dependent nucleosome remodellers is the ISWI family, first identified in yeast<sup>9</sup>. Mammals have two ISWI homologues *SNF2H* (*SNF2* homologue; human *SMARCA5*) and *SNF2L* (*SNF2*-like; human *SMARCA1*) that are the orthologs of yeast *Isw1* and *Isw2* genes<sup>10</sup>. ISWI can assemble regularly spaced nucleosomal arrays *in vitro* alone, or within a diverse number of protein complexes many of which contain a BAZ-family transcription factor (TF)<sup>11</sup>. ISWI complexes regulate many nuclear processes including DNA replication and repair (ACF, CHRAC and WICH), transcriptional regulation (NURF, RSF and CERF), and nucleolar structure and function (NoRC)<sup>11</sup>. ISWI inactivation in *Drosophila* also highlighted a role in higher-order chromatin structure<sup>12</sup>. However, despite a good understanding of the *in vitro* biochemical properties of ISWI and its related complexes, their *in vivo* roles remain poorly characterized.

In the murine central nervous system (CNS), *Snf2h* and *Snf2l* display dynamic patterns of expression, where *Snf2h* expression peaks in neuronal progenitors, while *Snf2l* is expressed predominantly in terminally differentiated neurons<sup>10</sup>. For this reason, we postulated that *Snf2h* and *Snf2l* might regulate the transition from a progenitor to a differentiated neuron to restrict and compact chromatin while poising other genes for expression. In this regard, catalytically inactive *Snf2l* mice exhibit hypercellularity of cortical progenitors and delayed their differentiation, resulting in a larger brain<sup>13</sup>. However, *Snf2h* knockout (KO) mice die at the peri-implantation stage due to growth arrest of the trophoctoderm and inner cell mass, thereby preventing the study of *Snf2h* during brain development<sup>14</sup>. To overcome this problem we describe the generation of an *Snf2h*-targeted allele that facilitated its characterization throughout mouse brain development. Our studies reveal that *Snf2h* controls higher-order chromatin organization to mediate the establishment of gene expression programs underlying cerebellar morphogenesis and neural maturation.

## Results

### *Snf2h* and *Snf2l* are developmentally regulated in the cerebellum.

The closely related mammalian ISWI genes, *Snf2h* and *Snf2l*, display complementary expression patterns that suggest they have distinct roles during tissue development<sup>10</sup>. Embryonic brain mRNA and protein expression analyses reveals that *Snf2h* is robustly expressed in the developing rhombic lip, similarly to the

hindbrain patterning TFs *Engrailed-1* (*En1*) and *Engrailed-2* (*En2*), whereas *Snf2l* expression was not detected within the rhombic lip at embryonic day (E) 14.5 (Fig. 1a–e). During late embryonic development, we observed robust *Snf2h* expression in developing Purkinje cells (PCs; Fig. 1f), mature PCs (Fig. 1g,i) and in nearly all NeuroD1+ neural lineages (Fig. 1h and Supplementary Fig. 1a,b). In contrast, *Snf2l* expression was prominent only within PCs after P7 (Fig. 1i and Supplementary Fig. 1c). Immunoblots of hindbrain and cerebellar extracts demonstrated that *Snf2h* levels peaked during the period of granule neuron progenitor (GNP) proliferation (~E18 to P7), whereas *Snf2l* levels increased as a function of cerebellar maturity with peak expression after ~P10 (Fig. 1j,k). Interestingly, *Snf2h* downregulation after P7 coincides with *En1* downregulation, whereas *En2* expression is robust throughout cerebellar development (Fig. 1j,k). Expression of all proteins was maintained in adulthood, albeit at lower levels (Fig. 1j,k). We conclude that *Snf2h* is robustly expressed in hindbrain progenitors while *Snf2h* and *Snf2l* protein levels are dynamically modulated during post-natal development.

**Generation and characterization of *Snf2h* cKO mice.** To investigate the significance of ISWI expression changes within the cerebellum we proceeded to generate *Snf2h* conditional KO mice since *Snf2h* germline KO mice die at the peri-implantation stage<sup>14</sup>. We inserted loxP sites flanking exon 5, which encodes the evolutionarily conserved ATP-binding pocket critical for remodelling activity (Fig. 2a,b)<sup>15</sup>. *Snf2h*<sup>-f/f</sup> mice were bred with a Nestin-Cre driver line that demonstrated Cre expression in neural progenitors by ~E11 and displayed robust Cre activity in cerebellar progenitors during the early post-natal period (Supplementary Fig. 2)<sup>16</sup>. *Snf2h*<sup>-f/f::Nestin-Cre</sup> conditional KO mice (*Snf2h* cKO-Nes hereon) were born at normal Mendelian ratios, but had a significant reduction in body weight by P7 (Fig. 2c), and were approximately half the size of control littermates by P20 (Fig. 2d). Brains isolated from these animals were reduced in size with striking cerebellar hypoplasia by P40 (Fig. 2e). Immunoblots of P0 cerebellar extracts confirmed an ~90% reduction in *Snf2h* protein levels (Fig. 2f). Three different behavioural assays demonstrated that *Snf2h* cKO mice have severe motor defects (Fig. 2g). We observed ataxia-like symptoms that began at ~P10, became severe by ~P15 to P20 and clearly contributed to the premature death of *Snf2h* cKO animals by ~P25 to P40 (Fig. 2h and Supplementary Movies 1–5). Concomitantly, *Snf2h*<sup>-f/f</sup> mice bred onto our *Snf2l*<sup>-f/f</sup> line were then crossed with the Nestin-Cre driver line to generate animals deficient for both ISWI genes (*Snf2h* and *Snf2l*)<sup>13</sup>. However, these cDKO-Nes mice did not survive past birth (Fig. 2h).

To further elucidate the contribution of *Snf2h* to cerebellar function, we generated a second strain of *Snf2h* cKO mice using the PCP2-Cre driver line that becomes active specifically in post-mitotic PCs after P10 (ref. 17; Supplementary Fig. 3). *Snf2h* cKO-PCP2 and cDKO-PCP2 were both born at normal Mendelian ratios and survived into adulthood (Fig. 2h). As such, we assessed the performance of *Snf2h* cKO-PCP2 animals in a cohort of motor and cognitive behavioural assays. We observed an enhanced performance in the rotating rotarod (Fig. 2i), but no additional alterations in motor control or spatial learning (Supplementary Fig. 4). In the fear-conditioning assay, the mice are exposed to a novel cue (cue tone), followed by a foot-shock (context), and the 'fear' response is measured (conditional response)<sup>18</sup>. *Snf2h* cKO-PCP2 mice had a normal response to the cue tone, but a reduced response to the context, suggestive of impaired associative learning skills (Fig. 2j). The social interaction

Values denote averaged densitometry,  $n = 4$ . (g) Dowel, hanging wire and elevated platform tests reveal severe motor abnormalities in *Snf2h* cKO-Nes mice relative to control littermates at P20–P25. \*\* $P < 0.01$ , one-way ANOVA,  $n = 10-14$ . (h) Kaplan-Meier survival curves of *Snf2h* cKO-Nes, cDKO-Nes and control littermates. *Snf2h* cKO-Nes mice were not viable under standard laboratory conditions after ~P30–P45, while cDKO-Nes mice did not survive past birth,  $n = 20-30$ . (i) Rotarod test: *Snf2h* cKO-PCP2 exhibit enhanced ability to stay on the rotarod after five sessions of training relative to controls. \*\* $P < 0.01$ , one-way ANOVA,  $n = 10-14$ . (j) Fear conditioning test: *Snf2h* cKO-PCP2 exhibit no differences in freezing response during training, but a decreased freezing response in context-dependent learning relative to controls. \* $P < 0.05$ , one-way ANOVA,  $n = 10-14$ . (k) Social interaction test: *Snf2h* cKO-PCP2 exhibit reduced interaction time with a stranger mouse in a controlled social environment relative to control littermates. \* $P < 0.05$ , one-way ANOVA,  $n = 10-14$ . Values are presented as the mean  $\pm$  s.e.m.

assay measures the preference of mice to interact with a stranger mouse over an inanimate object. *Snf2h* cKO-PCP2 mice spent less time interacting with the stranger mouse than control littermates (Fig. 2k). We conclude that the loss of *Snf2h* in post-mitotic PCs does not result in motor deficits but rather in cognitive alterations.

***Snf2h* loss affects GNP and PC progenitor expansion.** Since previous studies have highlighted a role for *Snf2h*-containing CRCs during DNA replication<sup>19,20</sup>, we assessed whether the cerebellar hypoplasia in *Snf2h* cKO-Nes mice resulted from poor

GNP or PC expansion. First, we examined the expression of proliferation markers in GNPs residing in the external granule layer (EGL) at E17.5 and E18.5. This analysis revealed that the proportions of cycling (Ki67<sup>+</sup>), mitotic (phosphorylated histone H3<sup>+</sup>, pH3<sup>+</sup>) and S-phase (BrdU<sup>+</sup>) cells were specifically reduced in the EGL of *Snf2h* cKO-Nes embryos (Fig. 3a–c). The proliferation defects coincided with a dramatic increase in cell death, as shown by an increased number of TUNEL<sup>+</sup> cells at E17 and P0 relative to controls (Fig. 3c). Moreover, measurements of the EGL showed that it was significantly reduced in size at P7 (Fig. 3d). Reduced proliferation in the *Snf2h* mutant cerebellum is in stark contrast to *Snf2l* deficient animals

**Figure 3** | *Snf2h* loss results in intrinsic GNP cell death without altering *Shh* signalling. (a) E17.5 sagittal cerebellar sections from *Snf2h* cKO-Nes and control littermates immunolabelled for phosphorylated Histone H3 (phospho-H3) or Ki67, and counterstained with the nuclear marker DAPI. Note a severe reduction of cells undergoing mitosis or S-phase throughout the mutant EGL (arrows). EGL, external granular layer. Scale bar, 100  $\mu$ m. (b) Confocal Z-stacks through the E18.5 and P3 cerebellum from *Snf2h* cKO-Nes and control littermates immunolabelled for BrdU after a 90-min BrdU-pulse (arrows). Scale bars, 100  $\mu$ m. (c) Quantification of BrdU+, Ki67+, phospho-H3+ or TUNEL+ cells throughout the mutant and control EGL at E17.5 and P0. \*\* $P < 0.01$ , Student's *t*-test,  $n = 4$ . (d) EGL size at P7 and P14 in *Snf2h* cKO-Nes and control littermates. \*\* $P < 0.01$ , student's *t*-test. n.s., not significant,  $n = 4$ . Values are presented as the mean  $\pm$  s.e.m. for c,d. (e) *In situ* hybridization through the cerebellar vermis from E18.5 *Snf2h* cKO-Nes and control littermates for *Sonic Hedgehog* (*Shh*), its receptor *Patched-1*, and their downstream target *Gli-1*. Note the spatiotemporal expression gradients (anterior high, posterior low) observed in both genotypes. Scale bar, 200  $\mu$ m. Boxed areas are shown in rightmost panels to highlight robust mRNA levels in both genotypes. Scale bar, 50  $\mu$ m. At least three mice from each genotype were used for evaluation.

where we observed increased proliferation and delayed differentiation of cortical progenitors<sup>13</sup>.

It is well established that the signalling factor *Sonic Hedgehog* (*Shh*) is secreted from PCs and plays a key role during GNP expansion and cerebellar foliation<sup>21–23</sup>. To assess whether poor GNP proliferation resulted from impaired *Shh* signalling, we examined the expression of *Shh* and its receptor, *Patched-1*, as well as the downstream effectors *Gli-1*, *CyclinD1* and *N-Myc* by *in situ* hybridization. Sagittal sections through the cerebellar vermis from E18.5 *Snf2h* cKO-Nes and control littermates showed that surviving PCs secrete *Shh* normally, and that all downstream targets are activated in surviving GNPs (Fig. 3e and Supplementary Fig. 5a).

To investigate PC progenitor proliferation, we birthdated cells by BrdU injection at E12.5 and harvested embryos at E17.5 for analysis<sup>24</sup>. *Snf2h* cKO-Nes embryos showed a significant reduction

in the proportion of BrdU+, Calbindin+ PCs relative to controls (Fig. 4a,d). Additionally, BrdU-birthdating at E18.5 with analysis at P7 revealed that reduced GNP proliferation in *Snf2h* cKO-Nes mice resulted in a dramatic reduction in the number of BrdU+ GCs but not Calbindin+ PCs, residing within the internal granule layer (IGL), relative to controls (Fig. 4b). However, co-staining with Pax6 and NeuN demonstrated that the timing of neuronal differentiation was not affected (Fig. 4c). Moreover, a normal percentage of BrdU+, GFAP+ glial cells within the white matter suggested that the reduced cellular output was specific to neurons (Fig. 4d and Supplementary Fig. 5b).

Taken together, these results suggest that the extrinsic cues (that is, *Shh* pathway) for progenitor expansion are unaltered and that the poor GNP and PC expansion in *Snf2h* cKO-Nes mice results from a cell-intrinsic defect, most likely from known ISWI functions in transcriptional regulation and DNA replication.

**Figure 4 | *Snf2h* loss affects PC and GNP expansion resulting in cerebellar hypoplasia.** (a) Confocal Z-stacks from *Snf2h* cKO-Nes and control littermates that were BrdU-birthdated at E12.5, a time of PC birth, and co-labelled for BrdU (green) and Calbindin (red) at E17.5 (brackets). Note the reduction of BrdU +, Calbindin + PCs in mutant embryos (arrows). Scale bar, 50  $\mu$ m. (b) Confocal Z-stacks from *Snf2h* cKO-Nes and control littermates that were BrdU-birthdated at E18.5, a time of robust GNP expansion, and co-labelled for BrdU (green) and Calbindin (red) at P7. DAPI (blue) stains all nuclei. Note the spatiotemporal (anterior low, posterior high) distribution of BrdU + GCs throughout the internal granule layer in control cerebella that is altered in mutant brains. DCN, deep cerebellar nuclei. Scale bar, 100  $\mu$ m. (c) Confocal Z-stacks through the cerebellar vermis from *Snf2h* cKO-Nes and control littermates that were BrdU-birthdated at E18.5, and labelled for BrdU (magenta); or co-labelled for Pax6 (red) and NeuN (green) at P7. DAPI (blue) stains all nuclei. Scale bar, 50  $\mu$ m. At least three mice from each genotype were used for evaluation. (d) Quantification of double-labelled BrdU + and Calbindin + PCs at E17.5 (E12.5 BrdU birthdating); double-labelled BrdU + and NeuN + GCs at P7 (E18.5 BrdU-birthdating); or double-labelled BrdU + and GFAP + glial cells from mutant and control mice at P7 (E18.5 BrdU-birthdating). \*\* $P < 0.01$ , Student's *t*-test. n.s., not significant,  $n = 3$ . Values are presented as the mean  $\pm$  s.e.m.

***Snf2h* and *Snf2l* co-modulate the *En1* locus.** In *Drosophila*, ISWI binding is enriched at transcriptional start sites where it influences gene transcription by repositioning nucleosomes<sup>25</sup>. We reasoned that altered nucleosome spacing within key developmental genes might perturb their expression and contribute to the impaired cerebellar development in the *Snf2h* cKO-Nes mice. Array hybridization of RNA isolated from mutant and control cerebella identified 110 genes differentially expressed at P0 that increased to 2,916 transcripts at P10 ( $P < 0.01$ ,  $n = 3$  per genotype, statistics was carried out using WEBARRAY online tool (<http://www.webarraydb.org/webarray/index.html>), which utilizes linear model statistical analysis (modified *t*-test)). Gene

ontology analysis using the DAVID online tool (<http://david.abcc.ncifcrf.gov/>) revealed significant enrichment ( $P < 0.05$ ) for downregulated genes associated with transcriptional regulation, cell adhesion and pattern specification (Fig. 5). We further filtered our P0 and P10 microarrays with publicly available RNA-Seq data from isolated adult PCs, GCs and Bergmann glia, to assign a specific cerebellar cell type to the gene expression changes observed, where possible (for example, GNP/GC expression: *En2*, *Pax6*, *Uncx* and *NeuroD1*; PC expression: *protocadherin- $\beta$*  (*Pcdh- $\beta$* ) isoforms; Supplementary Data 1)<sup>26</sup>. Validation of the microarray results by qRT-PCR confirmed that the expression of the TFs *Rfx3*, *Uncx*, *Cbp*, *Math1*, *Pax6*, *En2*, *En1*; the signalling

**Figure 5 | List of downregulated genes at P0 and corresponding gene expression changes at P10 from *Snf2h* cKO-Nes cerebella.** Cyan highlights TFs and yellow highlights cell adhesion molecules. Note that ~110 genes were deregulated at P0, while ~2,900 genes were deregulated at P10. Three microarrays per genotype were averaged from wild-type and mutant P0 and P10 cerebellar extracts. Underlined values denote  $P < 0.05$ . Statistics was carried out using WEBARRAY online tool (<http://www.webarraydb.org/webarray/index.html>) that utilizes linear model statistical analysis (modified *t*-test).

factor *Bmp4* and the cell adhesion molecules *Pcdh-β6* and *Pcdh-β17* were all significantly downregulated (~1.5–2.5-fold) in mutant cerebella at birth (Fig. 6a; Supplementary Table 1). Moreover, we observed a ~2.6-fold downregulation of *Snf2h*, while *Snf2l* levels were unperturbed in mutant cerebella at this time point (Fig. 6a). While most genes analysed remained downregulated at P10, we observed an unexpected increase in *En1* (~1.9-fold), *Bmp4* (~2.1-fold) and *Snf2l* (~1.7-fold) mRNA levels (Fig. 6a), the latter suggesting that *Snf2l* may be compensating for *Snf2h* loss in the activation of some targets. In this regard, P10 immunoblots demonstrated that *Snf2l* protein levels were increased by ~2.3-fold, whereas *Snf2h* protein levels were decreased by ~2-fold (Fig. 6b). *Snf2l* immunolabelling at P7 revealed comparable expression levels throughout the PC layer (Fig. 6c). We next investigated whether *Snf2l* could be responsible for the upregulation of genes at P10 that were reduced at P0, focusing our attention on *En1*.

The *En1* and *En2* homeobox genes are essential for cerebellar patterning and foliation<sup>27</sup>. During early post-natal development they adopt distinct expression patterns with *En1* and *En2* expressed in PCs and GCs, respectively<sup>28</sup>. Since *Snf2l* expression is limited to PCs (Fig. 1i and Supplementary Fig. 1c), we reasoned that upregulation of *En1* but not *En2*

might occur from *Snf2l* compensation. P7 sections through the cerebellar vermis were labelled with pan-Engrailed (Engrailed) antibodies, counterstained with DAPI and quantified for Engrailed immunoreactivity (-ir) within PCs (identified by their large nuclear size, >10 μm) from a minimum of 50 cells per genotype. We found that *Snf2h* cKO-Nes and control PC nuclei showed no significant differences in Engrailed-ir (Fig. 6d). However, the PCs of *Snf2h* cKO-PCP2 mice showed a significant reduction in Engrailed-ir, suggesting that *Snf2l* compensation is temporally regulated (Fig. 6e).

Given that *Snf2l* compensates for embryonic *Snf2h* loss, we next investigated whether reducing *Snf2l* levels would increase the severity of the phenotype. Indeed, removal of one copy of *Snf2l* on the *Snf2h* cKO-Nes background (*Snf2l*<sup>-/+</sup>;*Snf2h* cKO-Nes) resulted in a more severe ataxic phenotype and death by ~P25 (Fig. 6f and Supplementary Movie 6). As discussed earlier, the cDKO-Nes mice had the most severe phenotype, resulting in death at birth (Fig. 6f), which is comparable to the neonatal lethality of *En1* KO mice<sup>29</sup>. Microarray and immunostaining suggested that the *Snf2l* compensation begins between P0 and P7. Using immunoblots we were able to demonstrate *En1* compensation as early as P5 with *En2* expression reduced by ~60% (Fig. 6g). Similar results were observed at P20, suggesting

**Figure 6 | *Snf2h* and *Snf2l* co-modulate the *En1* locus.** (a) RT-qPCR analysis of selected genes from *Snf2h* cKO-Nes and control cerebella at P0 and P10. \**P* < 0.05, Student's *t*-test. n.s., not significant, *n* = 6 from one of two independent experiments. (b) Immunoblots for Snf2h and Snf2l from *Snf2h* cKO-Nes and control cerebellar extracts at P9. Scale bars, 50 μm (top); 10 μm (bottom). (e) Confocal Z-stacks of P30 cerebellum from *Snf2h* cKO-PCP2 and controls immunolabelled with Pan-Engrailed (red) and Calbindin (green). Engrailed images in bottom panel are pseudocolored (silver) for contrast. Scale bar, 5 μm. Values (d,e) denote Engrailed immunopixels normalized to WT within cells with a nuclear size > 10 μm<sup>2</sup> (circles). At least 50 PCs from three independent mice were quantified per genotype. (f) Kaplan-Meier curves of *Snf2l* KO, *Snf2l*<sup>-/+</sup>::*Snf2h* cKO-Nes and cDKO-Nes mice. Note that one *Snf2l* allele in a *Snf2h*-null background rescues the lethality of cDKO-Nes mice up to ~P25 (*n* = 25). (g,h) Immunoblots for Snf2l, Snf2h, En2 and En1 from *Snf2h* cKO-Nes and control cerebellar extracts at P5 (g) and P20 (h). Actin served as loading control. Values denote averaged densitometry (*n* = 4). (i) Top: schematic diagram of the mouse *En1* locus indicating primer set locations. Yellow boxes, 5' and 3' untranslated regions (UTRs); striped yellow boxes, coding region; black line = non-coding region; TSS, transcription start site (arrow); kb, kilobases away from the TSS (+1). Bottom: ChIP-qPCR from WT cerebellar extracts for the *En1* locus reveals Snf2h enrichment throughout the gene (R3, R2 and R1) at P7 and P21. Snf2l enrichment occurs only in the 5'-UTR (R2) at P21. \**P* < 0.05, Student's *t*-test, *n* = 4 from one of three independent experiments. Values are presented as the mean ± s.e.m. (j) Immunoblots for Snf2h, En2 and En1 from *Snf2h*<sup>+/+</sup>::*Snf2l*<sup>-/+</sup> (WT); *Snf2h*<sup>-/+</sup>::*Snf2l*<sup>-/+</sup> (*Snf2h* heterozygote); or *Snf2h*<sup>+/+</sup>::*Snf2l*<sup>-/-</sup> (*Snf2l* KO) cerebellar extracts at P9. Values denote averaged densitometry relative to WT levels (*n* = 4).

that both ISWI proteins mediate *En1* regulation, but *En2* regulation is specific to Snf2h (Fig. 6h). Furthermore, P5 immunoblots show reduced En1 levels in the *Snf2l*<sup>-/+</sup>::*Snf2h* cKO-Nes animals compared with *Snf2h* cKO-Nes mice, thus providing additional support for a *Snf2l*-dependent *En1* compensation in *Snf2h* cKO-Nes mice (Supplementary Fig. 6a).

To determine the interactions at the *En1* gene *in vivo*, we performed chromatin immunoprecipitation (ChIP) followed by quantitative PCR (ChIP-qPCR) assays for Snf2h and Snf2l with wild-type cerebellar extracts at P7, when Snf2h levels are at their

peak; and at P21, when Snf2l levels reach their maximal level. *En1* occupancy was analysed by qPCR with primer pairs corresponding to the intragenic region (R1), the 5'-UTR (R2), the proximal promoter (R3) and an upstream region (R4) (Fig. 6i). Snf2h binding showed the greatest enrichment at R2 at both time points with maximal binding observed at P7 (Fig. 6i). At P21, we also observed significant binding of Snf2l at R2 (Fig. 6i), suggesting that the ISWI proteins co-regulate *En1* transcription and that increased *Snf2l* expression provides functional compensation in *Snf2h* cKO-Nes mice. In contrast, only Snf2h was enriched at the

*En2* promoter (Supplementary Fig. 6b), providing further support for *Snf2h*-specific regulation of *En2*.

As a last step to understand the endogenous function of *Snf2h* and *Snf2l* during normal cerebellar development, we assessed *En1* and *En2* expression levels upon deletion of one *Snf2h* allele (*Snf2h*<sup>+/+</sup> versus *Snf2h*<sup>-/+</sup>) or upon complete ablation of *Snf2l* (*Snf2l*<sup>-/-</sup> versus *Snf2l*<sup>-/+</sup>). *Snf2h*<sup>-/+</sup> cerebella had a ~40% reduction of *En1* total protein levels, while *En2* and *Snf2h* protein levels were unaffected (Fig. 6j). Conversely, *Snf2l* deletion (*Snf2l*<sup>-/-</sup>; *Snf2l* is X-linked) resulted in a ~40% upregulation of *En1* protein levels, while *En2* and *Snf2h* protein levels remained unchanged (Fig. 6j).

Collectively, our results suggest that when both *Snf2h* and *Snf2l* are present the endogenous role of *Snf2l* is to function as a repressor of *En1* transcription, as *En1* protein levels are increased in *Snf2l* KO cerebella at P9. However, when *Snf2h* is ablated embryonically (*Snf2h* cKO-Nes model) we observed an upregulation of *Snf2l* that functionally compensates to restore *En1* expression and early PC functions (probably by substitution within *Snf2h* complexes). However, this novel gain-of-function effect by *Snf2l* is temporally regulated since it does not rescue *En1* expression when *Snf2h* is ablated at P10 (*Snf2h* cKO-PCP2 model). Moreover, *Snf2l* restoration of *En1* expression within the *Snf2h* cKO-Nes mice is insufficient to rescue the progressive ataxic phenotype.

***Snf2h* loss alters PC maturation.** The post-natal survival and progressive phenotype of *Snf2h* cKO-Nes mice allowed us to investigate the cell-intrinsic defects present in surviving post-mitotic neurons. For this analysis we chose the P7 cerebellum, a time when PC dendritic arbors extend towards the molecular layer for formation of parallel fibre circuits, while GCs migrate to the internal granule layer for establishment of mossy fibre circuitry<sup>24</sup>. We validated the loss of *Snf2h* in nearly all surviving Calbindin+ PCs (Fig. 7a), which were present in multiple PC layers compared with control PCs that were present in uniform developing rows (Fig. 7b). The growth of the molecular layer, which rapidly occurs between P7 and P14, was significantly reduced in size in the mutant animals (Fig. 7d). Indeed, a dramatic reduction of the PC apical dendritic arbor is observed with Golgi-Cox staining at P20, which is further aggravated in cDKO-Nes mice (Fig. 7c,f). In addition, we also observed a progressive and dose-dependent increase in the total number of PC pyknotic nuclei as assessed by toluidine blue staining (Fig. 7e).

The poor dendritic arborization and progressive death of PCs could be a consequence of the reduced number of cerebellar neurons that synapse onto the PC rather than an intrinsic defect in arborization. To investigate whether *Snf2h* is necessary for dendritic arborization and PC survival we further characterized the *Snf2h* cKO-PCP2 model, in which *Snf2h* loss is specific to PCs beginning at ~P10 (ref. 17). In this model, there is normal GNP proliferation resulting in a normally sized cerebellum and proper activation of post-mitotic markers in GCs and PCs, including *Pax6*, *Patched-1* and *Gli-1* (Supplementary Fig. 7a,c). However, we observed a significant reduction of the PC apical dendritic arbor by P30 (Fig. 7g,h). Moreover, *Snf2h* cKO-PCP2 mice also display an ISWI dose-dependent increase in the total number of pyknotic PCs between P50 and P300 (Supplementary Fig. 7b). Similar results from both *Snf2h* cKO mouse strains allow us to conclude that *Snf2h* plays a cell-autonomous role in post-mitotic PC maturation and survival.

***Snf2h* governs chromatin organization and histone H1 dynamics.** We reasoned that the progressive PC loss might result from altered chromatin architecture that impacts gene expression

and compromises cell function. Indeed, studies in yeast and *Drosophila* have demonstrated multiple roles for ISWI complexes in chromatin compaction by repositioning nucleosomes to mediate linker DNA length and by facilitating histone H1 deposition<sup>12,30,31</sup>. To assess chromatin organization, we examined nuclear ultrastructure of cerebellar neurons by transmission electron microscopy (TEM). TEM images of E18.5 *Snf2h* cKO-Nes mice revealed that GNPs and PCs display numerous densely stained clumps within the euchromatin, a dispersed nucleolar region, chromatin loops and structures indicative of nuclear invaginations or micronuclei that collectively indicate that the chromatin structure is highly disorganized (Fig. 8a). Moreover, we observed that the altered chromatin organization is augmented in cDKO-Nes mice at E18.5 (Fig. 8a, rightmost panel) and is progressive, both temporally and in a *Snf2l*-dose-dependent manner (Fig. 8b–e). Indeed, many pyknotic nuclei and cell ‘ghosts’ were clearly visible in *Snf2h* cKO-Nes mice by P21 (Fig. 8c). Collectively, these experiments demonstrate a progressive disorganization of the chromatin structure that correlates with the progressive death of GNPs and PCs, and the ataxic phenotype.

To confirm the cell-autonomous nature of the chromatin disorganization, we once again made use of *Snf2h* cKO-PCP2 mice. Sections from P50 mice were examined for chromatin ultrastructure changes by TEM. Similar to *Snf2h* cKO-Nes mice, we observed chromatin disorganization and loss of nuclear and nucleolar ultrastructure in P50 sections processed for TEM from *Snf2h* cKO-PCP2 but not from WT littermates (Fig. 8f).

The temporal increase in densely stained clumps and disorganized nucleolar structures likely contribute to the dramatic increase in deregulated gene expression we observed between P0 and P10. To address this we investigated whether any global perturbations in histone modifications occur during this time. Indeed, P9 immunoblots of acid-extracted histones from *Snf2h* cKO-Nes and control mice identified a significant decrease in histone marks for active transcription including H3K4Me3 and H3K18Ac, and for transcriptional elongation (H3K36Me2), but not for the repressive mark H3K9Me3 (Fig. 9a). We additionally found that the histone variants H2A.Z and macro-H2A, which mark regions of active or repressed chromatin, respectively, were normal at P2 but were markedly reduced in mutant cerebella by P9 (Fig. 9b). These results suggested that altered gene expression likely arises from a defect in establishing specific chromatin domains.

Studies in *Drosophila* have shown that *ISWI* ablation leads to global chromatin decompaction and a reduction in histone H1 (refs 12,31). As such, we analysed core histone proteins by immunoblot from *Snf2h* cKO-Nes mice and control cerebella at P2 and P9. At P2, all core histones were present at levels equivalent to wild-type mice (Fig. 9c). In contrast, we observed a severe reduction in histone H1 but not the other core histones by P9 (Fig. 9c,d). Interestingly, we noted that the H2A C-terminal antibody showed reduced detection of H2A at P9 but the N-terminal antibody showed normal levels, as did its dimer partner H2B (Fig. 9c,d). While this suggests that the epitope recognized by the C-terminal H2A antibody might be masked, modified or proteolytically cleaved, it remains unclear why we are observing this differential effect.

Recent studies have demonstrated that the C-terminal tail of histone H2A is required for histone H1 loading onto DNA and is also necessary for *Snf2h*-dependent nucleosome translocation<sup>32</sup>. Moreover, the reduced levels of H1 and the possibility that the H2A tail is modified or clipped in *Snf2h* cKO-Nes mice suggested that *Snf2h* regulates histone H1 dynamics. To decipher an *in vivo* role for *Snf2h* in H1 chromatin dynamics, we performed fluorescence recovery after photobleaching (FRAP) experiments

**Figure 7 | *Snf2h* loss alters PC maturation.** (a) *Snf2h* (red) and Calbindin (green) co-labelling through the cerebellum from *Snf2h* cKO-Nes and control littermates at P7. Note the absence of *Snf2h* expression in mutant PCs. Scale bar, 20  $\mu\text{m}$ . (b) Confocal Z-stacks through the cerebellar vermis from *Snf2h* cKO-Nes and control littermates at P7 immunolabelled for Calbindin (green). Roman numerals denote the corresponding lobules of the mammalian cerebellum. Scale bars, 100  $\mu\text{m}$  (left panels); 20  $\mu\text{m}$  (right panels). (c) Light microscopy Z-stacks of PCs through the cerebellar vermis stained with the Golgi-Cox method from *Snf2h* cKO-Nes mice and control littermates at P20. Scale bar, 10  $\mu\text{m}$ . (d) Molecular layer size at P7 and P14 in *Snf2h* cKO-Nes and control littermates. (e) Quantification of pyknotic PC nuclei using toluidine blue reveals an ISWI-dependent modulation of PC survival in *Snf2h* cKO-Nes, *Snf2l*<sup>-/+</sup>::*Snf2h* cKO-Nes and cDKO-Nes mice. (f,g) PC apical arbor dendritic length measurements from the indicated genotypes at P20 or P30, respectively. For panels (d-g) \*\* $P < 0.01$ , Student's *t*-test, n.s., not significant,  $n = 6$ . Values are presented as the mean  $\pm$  s.e.m. (h) Left panels: confocal Z-stacks through the cerebellum from P30 *Snf2h* cKO-PCP2 mice and control littermates co-immunolabelled for *Snf2h* (red) and calbindin (green). Arrows and bars denote mutant PC arbors that do not reach the pial surface (ps) (bars, arrows). Middle panels: higher magnification images of PCs (arrowheads) denote *Snf2h* + staining in control but not mutant PCs. Right panels: pseudocolored Calbindin-ir (silver) denotes the atrophied dendritic arbor in mutant PCs (bars, arrows). Scale bar, 20  $\mu\text{m}$  (left and rightmost panels); 10  $\mu\text{m}$  (middle panels). For a-c and h, at least three mice from each genotype were used for evaluation.

using GFP-H1e-tagged constructs transfected into Neuro2A cells before *Snf2h* knockdown (KD)<sup>33,34</sup>. To avoid any non-specific effects of cell death upon acute *Snf2h* ablation, FRAP experiments

were performed at the 48-h time point. The cell nucleus in both siScrambled (siScr) control and si*Snf2h*-treated cells appeared normal in size and shape at the time of the experiments (Fig. 9f).

**Figure 8 | *Snf2h* is necessary for proper chromatin folding.** (a) Transmission electron microscopy (TEM) of GNPs and PCs through the cerebellar vermis from *Snf2h* cKO-Nes, cDKO-Nes mice and control mice at E18.5. Red circles denote nuclear invaginations. GNP, granule neuron progenitor; PC, Purkinje cell; Nu, nucleus; No, nucleolus. Scale bars, 2  $\mu$ m. (b,c) TEM from *Snf2h* cKO-Nes and control mice through the cerebellum at P7 and P21. Note the abnormal morphology of mutant PCs and ‘cell ghosts’ in mutant cerebella. PC, Purkinje cell. Scale bars, 2  $\mu$ m. (d,e) TEM through the cerebellar vermis from control and *Snf2l*<sup>-/-</sup>::*Snf2h* cKO-Nes mice at P7, revealing the aggravation of chromatin ultrastructure abnormalities within PCs upon additional removal of one *Snf2l* copy. Boxed area is enlarged in bottom rightmost panel. Scale bars, 10  $\mu$ m (top panels); 2  $\mu$ m (bottom panels). (f) TEM from P50 *Snf2h* cKO-PCP2 mice and control littermates through the cerebellar vermis. Higher magnification images are provided in descending panels. Note the loss of nucleolar, heterochromatin and euchromatin ultrastructure and increased electron density, evidenced as ‘chromatin clumps’ within mutant PC nuclei. Stars denote nucleolar dense fibrillar centers (dfc). gc, granular centre; fc, fibrillar centre; no, nucleolus; eu, euchromatin; hch, heterochromatin. Scale bars, 2  $\mu$ m (top panels); 500 nm (middle and bottom panels). At least three mice from each genotype were used for evaluation.

si*Snf2h*-treated cells displayed an increased ‘bleached depth’ that suggests that the pool of unbound H1 is increased in the mutant samples. In addition to an increase in the unbound fraction, there was also a subtle change in H1 dynamics as we observed an  $\sim$ 10% reduction in histone H1e-GFP mobility and an  $\sim$ 20% increase in the half-maximal recovery time (*t*-half) compared with siScr controls (Fig. 9e–g and Supplementary Movies 7 and 8). To demonstrate that the observed effect was specific to *Snf2h*, we restored the mobility of GFP-H1e by co-transfecting hSNF2H (addback hSNF2H) that is unaffected by the siRNA treatment (Fig. 9e,g and Supplementary Movie 9). Conversely, *Snf2l* KD did not alter GFP-H1e dynamics (Supplementary

Fig. 8c). However, exogenous expression of hSNF2L was also able to rescue GFP-H1e dynamics following *Snf2h* KD (addback hSNF2L), which is indicative of the functional compensation we have observed in *Snf2h* cKO-Nes mice (Fig. 9e,g and Supplementary Movie 10). These studies suggest that *Snf2h* participates in the loading of histone H1 onto chromatin.

We next investigated whether acute KD of *Snf2h* by siRNA treatment in Neuro2A cells could recapitulate the chromatin changes we observed in the *Snf2h* cKO mice. We observed a significant KD of *Snf2h* by 48 h and  $>$ 90% loss by 96 h (Fig. 9h). We next analysed the cells for changes in nuclear morphology after DAPI staining. We observed a subtle reduction in the

**Figure 9 | Snf2h mediates chromatin transitions through linker histone H1 dynamics.** (a,b) Immunoblots of acid-extracted cerebellar histones from *Snf2h* cKO-Nes (*Snf2h*<sup>-/-</sup>) and control littermates (*Snf2h*<sup>-/+</sup>) for (a) histone H3 post-translational modifications at P9; or (b) histone variants H2A.Z and macro-H2A at P2 and P9. Values denote average densitometry relative to control samples ( $n=4$ ). (c) Immunoblots of core histones from P2 and P9 cerebellar extracts from *Snf2h* cKO-Nes and control littermates. Values denote average densitometry relative to control samples ( $n=4$ ). (d) Colloidal blue staining of isolated P2 and P9 histones from *Snf2h* cKO-Nes and control littermates to examine stoichiometry. (e) Mean normalized GFP-H1e FRAP curves of siScrambled (siScr); siSnf2h; siSnf2h + addback human (h) SNF2H; or siSnf2h + addback hSNF2L from transiently transfected mouse Neuro2A cells 48 h after treatment. A significant difference between recovery curves of siScrambled and siSnf2h is indicated.  $**P=0.008$ ,  $n=20$ , Student's *t*-test. Error bars were omitted for clarity. (f) FRAP images of GFP-H1e from siScr (top) or siSnf2h (bottom) Neuro2A treated cells at the indicated times. Scale bar, 1  $\mu$ m. (g) Mobile fractions and t-half values for GFP-H1e FRAP experiments.  $**P=0.008$ ,  $n=20$ , Student's *t*-test. (h) Histone immunoblots of Neuro2A cells treated with siScr or siSnf2h for the indicated times. Snf2h KD is observed by 48 h. Actin served as loading control. Values denote average densitometry relative to siSnf2h 24 h treatment. ( $n=4$ ). (i) Proposed model of Snf2h-dependent chromatin organization. Left, Snf2h interacts with the C-terminal tail of H2A to mediate histone H1 deposition and promote higher-order chromatin compaction and terminal differentiation<sup>32</sup>. Right-top, Snf2h is required for normal progression through the cell cycle<sup>35,37</sup>. *Snf2h* cKO-Nes mice have compromised expansion of the GNP and PC progenitor pools resulting in cerebellar atrophy. Right-bottom, after cell cycle exit, Snf2h- and Snf2l-dependent chromatin remodelling drives the establishment and maintenance of gene expression profiles. The co-regulation at the *En1* locus is depicted as an example and this regulation promotes neural maturation. The embryonic removal of Snf2h (Nestin model) results in cerebellar hypoplasia and reduced dendritic arborization of PCs, causing severe ataxia and premature death. Similarly, Snf2h ablation in PCs (PCP2 model) also affects PC arborization, but conversely results in cognitive deficits rather than motor alterations.

number of DAPI dense foci at 48 h and this preceded activation of phosphorylated Caspase-3, which was only detectable at 96 h after siSnf2h KD (Supplementary Fig. 8a,b). Despite significant Snf2h KD we only observed a modest  $\sim 20\%$  decrease in histone H1 by 96 h after siSnf2h treatment (Fig. 9h). The core histones H3 and H4 showed no change, although we observed an unexplained increase in H2A and H2B protein levels. Similar to our results with the P9 cerebellar extracts, we observed a dramatic loss of H2A signal using the C-terminal H2A antibody (Fig. 9h). In addition, we also observed reduced signal with two H2A C-terminal tail modifications, namely phosphorylation of T120

and ubiquitination at K119 (Fig. 9h). While suggestive of a H2A C-terminal tail modification upon Snf2h loss, we were unable to identify the nature of such a change. Nonetheless, our studies indicate that an integral relationship between Snf2h, H1 and H2A is critical for chromatin folding and gene expression during cerebellar development (Fig. 9i).

## Discussion

Ablation of Snf2h results in the loss of functional ACF/CHRA, WICH and NoRC remodelling complexes that collectively have a

major impact on the dynamics and organization of chromatin. Indeed, altered chromatin dynamics impaired cerebellar progenitor expansion, the transcription of key cerebellar patterning genes and the morphological maturation of PCs. As a result, *Snf2h* cKO-Nes mice developed cerebellar ataxia that resulted in their premature death, while *Snf2h* cKO-PCP2 had a normal lifespan, but displayed cognitive deficits and progressive PC death.

A key feature of the developing post-natal cerebellum is the massive expansion of GNPs, a critical event in cerebellar foliation<sup>24</sup>. We demonstrate that the reduced cerebellar size in *Snf2h* cKO-Nes mice results from a combination of poor GNP and PC proliferation, without altering *Shh* signalling. Several studies have implicated ACF/CHRAC and WICH complexes in the replication of heterochromatin<sup>19,20</sup>. The WICH complex acts behind the replication fork to re-establish the local chromatin environment while the ACF/CHRAC complex is recruited as part of the DNA damage checkpoint response to collapsed replication forks<sup>35</sup>. Indeed, defective replication of heterochromatin is known to result in DNA damage, mitotic catastrophe and cell death, which can have a significant effect on cell number during the proliferative phase of tissue growth<sup>36,37</sup>. This would be consistent with our findings of increased TUNEL staining in *Snf2h* cKO-Nes mice at the onset of GNP expansion. Similarly, RNAi depletion in HeLa or U2OS cells results in increased apoptosis 24 h after SNF2H or ACF1 protein expression was strongly reduced<sup>37,38</sup>. Nonetheless, several alternative explanations exist that could account for the decreased growth of the cerebellum. Reduction of histone H1 may be sufficient to induce cell cycle arrest, as found with H3 ablation studies in yeast<sup>39</sup>. Similarly, reduced expression of *Engrailed* and/or other GNP or PC-specific TFs may impair growth, particularly since mouse models null for *Pax6*, *Math1*, *NeuroD1*, *En2* or *En1* result in cerebellar hypoplasia<sup>40–43</sup>. Regardless, our experiments demonstrate a requirement for Snf2h in the proliferation of GNPs and PCs and the subsequent foliation of the cerebellum during the post-natal period.

Purkinje neurons are critical for cerebellar function and we demonstrate that Snf2h is important for the maturation and function of this cell type. We show that dendritic arborization was compromised using two different Cre-driver lines (Nestin-Cre and PCP2-Cre) to ablate Snf2h. In the *Snf2h* cKO-Nes model, the poor arborization resulted in severe motor deficits that we attribute to the combined loss of both PCs and GCs. Conversely, the *Snf2h* cKO-PCP2 model presented with cognitive abnormalities reminiscent of the Purkinje-specific *Tsc1* mouse strain with autistic-like features<sup>44</sup>. Indeed, dendritic defects and aberrant synaptic plasticity are common phenotypes for mouse strains inactivated for chromatin remodelling proteins<sup>45,46</sup>. Recent evidence shows that epigenetic regulation of synaptic plasticity extends beyond development, since electrophysiological deficits can be rescued by re-introduction of the missing CRC subunit in post-mitotic neurons<sup>47</sup>. Similar studies are required to dissect the individual roles of *Snf2h*-associated subunits to PC synaptic physiology and cognitive functions. In this regard, we are currently exploring whether environmental enrichment or *in vivo* re-introduction of Snf2h can rescue the motor dysfunction in *Snf2h* cKO-Nes mice.

We surmise that the dendritic defects arise from aberrant transcription of target genes, particularly given the rampant increase in deregulated genes between birth and P10 (110 genes at P0 versus ~2,900 genes at P10). High-throughput CHIP-Sequencing studies from *Drosophila* and mouse cell lines indicate that ISWI and Snf2h interact at genes ~300 bp downstream of the transcriptional start site where it localizes nucleosomes into positions that stabilize a transcriptional (active or repressed) state<sup>25,48</sup>. Indeed, we observed enrichment for both Snf2h and

Snf2l in a similar position at the *En1* locus. The specific positioning of nucleosomes by Snf2h may also facilitate the loading of H2A.Z in progenitors, which acts to 'poise' genes for expression upon differentiation<sup>4</sup>. An inability to position nucleosomes around the promoter or exchange H2A for H2A.Z or macro-H2A may account for the poor regulation we observed for many genes by P10. It is also possible that Snf2h and Snf2l impart exquisite transcriptional control on developmentally important genes, as suggested by the function of known targets<sup>13,49,50</sup>. For example, *Foxg1* levels determine whether a progenitor undergoes self-renewal or differentiation<sup>51</sup> and *Snf2l* mutant mice had increased *Foxg1* expression that enhanced progenitor proliferation and increased brain size<sup>13</sup>. Similarly, the interaction of both Snf2h and Snf2l at the *En1* gene (co-modulation) may regulate its expression levels and/or recruitment to target loci to control PC maturation, as has been observed for the TF Olig2 and the chromatin remodeller Brg1 during oligodendrocyte differentiation<sup>52</sup>. We propose that Snf2h poises and/or triggers the *En1* locus for activation, while Snf2l is turned on during late cerebellar development to tightly modulate (i.e. repress) *En1* levels in the mature PC. Certainly, the interaction at co-modulated target genes may facilitate rapid and dynamic changes in gene expression induced by extrinsic signals.

Genome wide epigenetic profiling experiments have supported the hypothesis that neurogenesis is accompanied by the transition of a highly dynamic chromatin environment within progenitor cells to a more restrictive epigenetic landscape that dictates gene expression programmes specific to each lineage<sup>2,3</sup>. Chromatin condensation is dependent on nucleosome repeat length and the incorporation of the linker histone H1 (ref. 6,7). *In vitro* studies have shown that ISWI protein complexes assemble and evenly space nucleosomes on a chromatin template<sup>11</sup>, while loss of ISWI function in *Drosophila* results in reduced histone H1 levels and the decondensation of the X chromosome<sup>12,30,31</sup>. Other studies have noted a requirement for NoRC in the formation of perinucleolar heterochromatin structures<sup>53</sup>. In this regard, we observed a wide range of chromatin changes in *Snf2h* cKO mice both by TEM and immunoblot including patches of condensed euchromatin, loss of histone H1, altered levels of specific histone marks and histone variants, and disorganized nucleolar structures that collectively indicate that chromatin organization is abnormal. As discussed above, aberrant heterochromatin formation during replication could lead to mitotic catastrophe and cell death of the GNPs, thereby accounting for the cerebellar hypoplasia we observed. In addition, aberrant nucleosome spacing and maintenance of nucleosome-free regions could disrupt gene expression programs that could result in the maturation defects we observed and the progressive cell death, perhaps initiated in a cell with an inability to respond to an external signal. While we favour the idea that Snf2h loss promotes changes in chromatin structure directly, resulting in an inability to function and subsequent death, we cannot rule out that the chromatin disorganization we observed in *Snf2h*-null cells is indirect and representative of cells that were in the early stages of programmed cell death. Future studies will aim to distinguish between these possibilities.

Higher-order chromatin packaging is dependent on histone H1 as embryos lacking three histone H1 subtypes (H1c, H1d and H1e) die by mid-gestation with a broad range of defects<sup>54</sup>. Histone H1 has been shown to play a key role in silencing gene expression by tethering Su(var)3–9 to heterochromatin<sup>55</sup>. Unlike core histones, which display very slow kinetics with residence time in the range of hours, linker histones are highly mobile, and more recently were shown to have metastable states with partially bound molecules<sup>56,57</sup>. Indeed, H1 dynamics reflects cell plasticity and chromatin compaction in general<sup>33</sup>. This may explain the

modest ~10% reduction in H1e-GFP mobility observed upon *Snf2h* depletion in Neuro2A cells. Whereas this mobility was restored upon hSNF2H or hSNF2L overexpression, these measurements may only reflect the unbound H1 pool. Nonetheless, our evidence suggests that *Snf2h* loss results in abnormal higher-order chromatin packaging that disrupts genome organization and chromatin fluidity.

Recent studies have demonstrated that the C-terminal tail of histone H2A is required for histone H1 loading and for *Snf2h*-dependent nucleosome translocation<sup>32</sup>. Indeed, the altered H1 levels and abnormal H2A post-translational processing in *Snf2h* cKO-Nes mice is suggestive of a functional relationship between *Snf2h*, histone H1 and H2A. We propose that an interaction between H2A and *Snf2h* may alter the accessibility of the H2A C-tail for loading histone H1 onto chromatin to facilitate chromatin packaging. In this regard, biochemical studies have shown that removal of the H2A C-tail increased the mobility of nucleosomes *in vitro*<sup>32,58</sup>. Such a mechanism for increasing the mobility of the nucleosome may be a compensatory response in the *Snf2h* cKO mice to facilitate nucleosome spacing and chromatin compaction, a function normally provided by *Snf2h*-dependent chromatin remodelling. In addition, *Snf2h* interactions with the H2A tail could promote H2A/H2B dimer removal and subsequent H2A variant exchange to activate and/or repress gene activity. Within progenitor cells these functions could mark genes for expression (H2A.Z loading) or repression (macro-H2A loading) upon differentiation, while establishing the restrictive chromatin landscape (through histone H1 loading) that accompanies the transition from progenitor expansion to terminal differentiation<sup>59,60</sup>. While exciting, such mechanisms remain speculative and the exact relationship between *Snf2h* loss and H2A C-tail post-translational processing remains to be deciphered with more biochemical studies. Indeed, delineating the epigenetic regulation of neuronal development is crucial to our understanding of intellectual-disability disorders caused by mutations in epigenetic modifying enzymes. As a whole, our findings highlight the complexity and functional diversity of *Snf2h*-containing CRCs during brain development, and their roles in controlling chromatin organization as cells modulate their chromatin environment from a 'largely open' progenitor state to the 'highly restricted' state of a fully differentiated neuron during cerebellar morphogenesis and neural maturation (Fig. 9i)<sup>60</sup>.

## Methods

**Generation of *Snf2h*<sup>fl/fl</sup> mice.** *Snf2h*<sup>exon5fl/exon5fl</sup> (*Snf2h*<sup>fl/fl</sup>) mice were generated through homologous recombination in WW6 ES cells as described<sup>14</sup>. Briefly, a 6.0-kb fragment of the *Snf2h* gene containing exons 4–8, into which loxP sites were inserted 5' and 3' of exon 5, was cloned into the pEasyFlirt vector (a gift of Dr M.P. Lisanti, University of Manchester, UK). This vector has a neomycin resistance gene flanked by Frt sites, which was removed in mice generated from correctly targeted ES cells by breeding to *Flp1* recombinase mice<sup>61</sup>. *Snf2h*<sup>fl/fl</sup> mice were viable, fertile and did not exhibit any gross behavioural abnormalities. Cre-mediated deletion of *Snf2h* exon 5 was tested by breeding to ZP3-Cre mice<sup>62</sup> for which embryos homozygous for a deleted exon 5 died *in utero* due to abnormal progenitor expansion, as previously described<sup>14</sup>.

**Mouse breeding.** *Snf2h*<sup>fl/fl</sup> mice were backcrossed for six generations to a C57Cl/6 background and bred with a C57Bl/6 Nestin-Cre<sup>-/+</sup> driver line<sup>16</sup> that also carried a *Snf2h* null allele<sup>14</sup>, thereby generating *Snf2h* cKO-Nes mice (*Snf2h*<sup>-/fl::Nes-Cre<sup>-/+</sup>). We also bred *Snf2h*<sup>fl/fl</sup> mice to the PCP2-Cre driver line<sup>17</sup> that lived normally into adulthood and showed no gross behavioural abnormalities. For *Snf2l* ablation, we used the previously characterized Ex6Del line<sup>13</sup> for breeding, thus generating *Snf2l*-*ly::Snf2h* cKO (cDKO-Nes) and *Snf2l*-*ly::Snf2h* cKO-PCP2 (cDKO-PCP2), as well as *Snf2l*-*+/+::Snf2h* cKO-Nes and *Snf2l*-*+/+::Snf2h* cKO-PCP2 compound heterozygotes. For embryo staging, embryonic day 0.5 (E0.5) was defined as noon on the day of vaginal plug detection. Animals were kept in an animal house under specific pathogen-free conditions in a 12/12 light:dark cycle with water and food *ad libitum*. The University of Ottawa Animal Care and Use Committee approved all experiments. C57Bl/6 and FVB/NJ wild type mice</sup>

were purchased from Charles River (Montreal, QC, Canada). PCP2-Cre mice were obtained from The Jackson Laboratory (Stock no. 004146; Bar Harbor, ME, USA).

**Behavioural analysis.** All behavioural tests were completed in the Behavior Core Facility at the University of Ottawa using standardized protocols. Animals were habituated to the testing room at least ~1 h before testing. Behavioural assays were performed irrespective of sex for *Snf2h* cKO-Nes mice and tested between P20–P25. For *Snf2h* cKO-PCP2 mice, female and male mice were assessed independently at 4–6 months of age, for which we did not observe sex-specific differences in behaviour and pooled the data. For behavioural assays, one-way ANOVA was used for at least 10 mice per genotype. The values are presented as the mean ± s.e.m.

**Suspended wire test.** Mice were suspended by their forepaws on a 2 mm wire, and the amount of time they remained on the wire was recorded.

**Dowel test.** Mice were placed in the centre of a horizontal pole (1 cm diameter) and the time mice remained on the pole was recorded. If mice walked across and off the dowel, they were placed back onto the dowel. Trials lasted for a maximum of 2 min.

**Elevated platform.** Mice were placed in the centre of a 15-cm<sup>2</sup> round elevated platform 50 cm above the ground and the time mice remained on the platform was recorded. Student's *t*-test was used for statistical significance.

**Rotarod.** Mice were trained and tested on the accelerated rotarod (rod diameter 3 cm) for 300 s for five times before measurements (IITC, Woodland Hills, CA, USA). Starting speed was set at 4 r.p.m. and maximum speed at 40 r.p.m. The latency to fall from the rotarod was recorded. If animals were able to stay on the rod for 300 s, the latency to fall recorded was 300 s. The animals received four trials per day, with a trial interval of 30 min, for 2 consecutive days.

**Pole test.** Mice were placed head-upward on the top of a rough surfaced vertical pole (8 mm diameter × 55 cm tall) and the time for descending recorded. The time required for the mouse to turn downward after placing and the total time on the pole until the mouse reaches the bottom is recorded. Mice were trained for 2 days before test. Five trials were averaged on day 3.

**Open field.** Animals were placed in the centre of a 45 × 45 × 45-cm chamber equipped with photobeams (Accuscan) to record activity during a 10-min test period.

**Elevated plus maze.** Animals were habituated to the test room for at least 2 days before test. Animals were placed in the centre of a maze consisting of two arms (each arm 5 cm wide × 60 cm long) enclosed by ~15-cm-high walls, and two open arms (each arm 25 × 7.5 cm, with a raised 0.5 cm lip at edges) elevated 1 metre above ground and with equidistant arms from the centre of the platform. The amount of time the animals spent in the open or closed arms, the total number of entries and the total distance travelled were recorded for 10 min using video detection software (Ethovision, Wageningen, Netherlands).

**Social interactions.** A control mouse is placed in the corner of an open field box (under dim red light) that measures 45 cm long on each side × 45 cm high and containing a 5.5 × 9.6 cm wire mesh rectangular cage. The mouse is given 5 min to explore the arena and then removed. A few seconds later, a test mouse (or social target) of the same strain, age and gender is placed inside the rectangular wire mesh cage and the control mouse placed back in the arena. The time the social target interacts with the control mouse in 5 min trials is recorded using Ethovision 7 XT automatic tracking software. Total distance travelled, time spent in two corners across the wire mesh cage and velocity is also recorded.

**Fear conditioning.** On the first day (training), the animal is placed in the fear-conditioning apparatus for a total of 6 min. After the first 2 min in the apparatus a tone is played for 30 s ending with a 2-s shock. One minute following the shock, the tone is played again for 30 s ending with a 2-s foot shock. For the remaining 2 min there is no tone or shock. The freezing behaviour of the animal is recorded throughout the 6 min. This is the training in which the mouse receives two exposures to the tone followed by the shock and this occurs in a novel context, which is the conditioning box. On the second day, contextual conditioned fear testing begins. This measures the fear associated with being in the same environment where the shock was delivered (done ~24 h after training). The mouse is placed in the same apparatus with all the same lighting and room conditioning for 6 min and freezing behaviour is recorded.

**BrdU-birthdating.** Timed-pregnant females were injected intraperitoneally with 100 µg per g body weight of 5-bromo-2'-deoxyuridine (BrdU; Sigma) and pups killed at indicated times. For BrdU-pulse labelling, timed-pregnant females were injected with BrdU and killed 90 min later. For BrdU immunodetection, sections were incubated in 2 N HCl for 10 min at 37 °C, rinsed in 0.1 M sodium borate

(pH 8.3), blocked and incubated overnight at 4 °C with rat monoclonal anti-BrdU antibody 1:300 (Abcam no. 6326). The average number of immunopositive cells was determined from five separate fields under  $\times 40$  magnification in confocal Z-stacks (or cubic bins) of  $18 \times 10^3 \mu\text{m}^3$ .

**TUNEL assay.** Sections were examined for DNA fragmentation with the TUNEL *in situ* cell death detection kit (Roche Applied Science, ON, Canada) according to the manufacturer's instructions. The average number of TUNEL-positive cells was determined from five separate fields under  $\times 40$  magnification in cubic bins.

**Golgi-Cox staining.** Golgi staining was completed using FD Rapid GolgiStain Kit (FD NeuroTechnologies). Briefly, P20 mice were intracardially perfused with 4% paraformaldehyde (PFA) in 0.1 M PBS and stained according to the manufacturer's instructions. Tissues were sectioned at 60–100  $\mu\text{m}$  and mounted on gelatin-coated slides.

**Immunofluorescent histochemistry.** For embryonic tissue, 16–20  $\mu\text{m}$  sections were used. For post-natal brains, 40–50  $\mu\text{m}$  free-floating sections were used. Sections were washed four times in PBST (PBS with 0.1% Triton X-100), blocked (1 h, room temperature (RT)) in 10% horse serum/PBST, and incubated (overnight, 4 °C) in primary antibodies. The following primary antibodies were used from Abcam: rabbit anti-Snf2h (1:500, no. 72499); rabbit anti-Snf2l (1:100, no. 37003); mouse anti-NeuroD1 (1:500, no. 60704); rat anti-BrdU (1:300; no. 6326) and rabbit anti-Engrailed (1:500; no. 32817). Mouse anti-calbindin (1:200, Sigma C9848); rabbit anti-calbindin (1:300, Sigma C2724); rabbit anti-GFP (1:1,000, Molecular Probes); mouse anti-BrdU (1:100, DAKO); rabbit anti-phospho histone H3 (pH3; 1:200; Millipore no. 06-570); rabbit anti-Pax6 (1:200; Covance no. PRB-278P); mouse anti-NeuN (1:200, Millipore no. MAB377) and rabbit anti-pan-Engrailed (gift of Dr Alexandra Joyner, Memorial Sloan-Kettering Cancer Center, NY, USA). The following day, sections were washed five times in PBST and incubated (2 h, RT) with DyLight<sup>488</sup>, DyLight<sup>594</sup> or DyLight<sup>649</sup>-conjugated mouse pre-adsorbed secondary antibodies (1:1,000, Jackson ImmunoResearch, PA, USA) against the IgG domains of the primary antibodies. All sections were counterstained with the nuclear marker DAPI (Invitrogen). Sections were mounted on slides with Dako Fluorescence Mounting Medium (Dako Canada, ON, Canada).

**X-Gal staining.** Staged embryos were quickly dissected and rinsed in 0.1 M PBS (pH 7.4) and fixed in 4% PFA for 30 min. Embryos were then rinsed three times with 0.1 M PBS supplemented with 0.01% Triton X-100 and incubated for  $\sim 1$  h in the dark with staining solution (2 mM MgCl<sub>2</sub>, 0.02% NP-40, 5 mM potassium ferricyanide, 5 mM potassium ferrocyanide and 0.01% sodium deoxycholate in 0.1 M PBS, pH 7.4). Staining solution was rinsed off three times with 0.1 M PBS and embryos post-fixed for 30 min in 4% PFA.

**In situ hybridization.** *In situ* hybridization was performed from E18.5 or P0 14–16  $\mu\text{m}$  sections through the cerebellar vermis using digoxigenin (DIG)-labelled antisense RNA riboprobes prepared by *in vitro* transcription from linearized plasmids containing complete or partial cDNA sequences of the following mouse genes: *Shh*, *Gli1*, *Mycn*, *Ptch1*, *Cend1* and *Pax6*. Labelling of RNA probes with DIG-UTP was performed according to the manufacturer's recommendations. Briefly, 1  $\mu\text{g}$  of linearized template was transcribed in a total volume of 20  $\mu\text{l}$  using T7 or T3 polymerase (Roche) and DIG-UTP (Roche) for 1 hour at 37 °C. The reaction products were precipitated, resuspended in 100  $\mu\text{l}$  of 10 mM EDTA and stored at  $-20$  °C. DIG-labelled RNA probes were diluted in hybridization buffer (50% formamide, 10% dextran sulphate, 1 mg ml<sup>-1</sup> yeast RNA, 1  $\times$  Denhardt's and 1  $\times$  salt) and denatured for 10 min at 70 °C. Sections were hybridized overnight at 65 °C in a humidified box. The slides were washed twice in 50% formamide, 1  $\times$  SSC, 0.1% Tween 20 at 65 °C for 30 min followed by two washes in MABT (100 mM maleic acid, 150 mM NaCl, pH 7.5, 0.1% Tween-20) for 30 min at RT. Sections were blocked for 1 h at RT in MABT containing 20% sheep serum (Sigma) and 2% blocking reagent (Roche). The blocking solution was then replaced with blocking solution containing a 1:1,500 dilution of alkaline-phosphatase-conjugated Fab fragments of sheep anti-DIG antibodies (Roche) and the slides were incubated overnight at 4 °C in a humidified box. Slides were washed five times in MABT for 20 min at RT, twice in staining buffer (100 mM NaCl, 50 mM MgCl<sub>2</sub>, 100 mM Tris pH 9.5 and 0.1% Tween-20) and incubated for 1–5 h in staining buffer containing 10% polyvinyl alcohol, 4.5  $\mu\text{l}$  ml<sup>-1</sup> NBT and 3.5  $\mu\text{l}$  ml<sup>-1</sup> BCIP (Roche) in the dark at RT. Slides were washed several times in 1  $\times$  PBS and mounted in 50:50 glycerol:PBS.

**Western blotting.** Cerebellar or hindbrain (for E12 and E17 time points only) extracts were quickly dissected from individual pups and snap-frozen in dry ice. Cerebella were then homogenized in ice-cold RIPA buffer supplemented with protease inhibitor cocktail (Sigma) and incubated for 20 min on ice with gentle mixing. After pre-clearing by centrifugation (15 min at 17,000 g), proteins were quantified by the Bradford method. Protein samples were resolved on sodium dodecyl sulphate polyacrylamide gels under denaturing conditions or using

Bis-Tris 4–12% and Tris-Acetate 3–8% gradient gels (NuPage, Invitrogen) and blotted onto PVDF membranes (Immobilion-P; Millipore, MA, USA) by wet transfer for 1–2 h at 90 V. Membranes were blocked (45 min, RT) with 5% skim milk in TBST (Tris-buffered saline containing 0.05% Triton X-100), and incubated (4 °C, overnight) with the following antibodies: rabbit anti-Snf2h (1:4,000; Abcam no. 72499); sheep anti-Snf2l (1:2,000)<sup>63</sup>; mouse monoclonal anti-Snf2l 1:1,000 (Alvarez-Saavedra and Picketts, unpublished); mouse anti- $\beta$ -actin (1:30,000, Sigma); rabbit anti-Engrailed-1 (1:2,000, Millipore) or mouse anti-Engrailed 4G11 (1:20, Developmental Studies Hybridoma Bank). Membranes were incubated (1 h, RT) with ImmunoPure HRP-conjugated goat anti-rabbit or goat anti-mouse IgG (H + L) secondary antibodies (1:50,000; Pierce, Rockford, IL, USA). Membranes were washed 5  $\times$  5 min in TBST after antibody incubations, and the signal was detected using the Pierce Supersignal West Femto chemiluminescence substrate (Pierce). Western blots were quantified using ImageJ software (rsbweb.nih.gov/ij/). At least four individual lanes from multiple litters were used for quantification. All original western blots are shown in Supplementary Fig. 9.

**Chromatin immunoprecipitation.** Cerebella was isolated from C57Bl/6 wild-type mice and cell pellets resuspended in 50 mM HEPES-KOH, pH 7.5, 140 mM NaCl, 1 mM EDTA, 1% Triton X-100, 0.1% sodium deoxycholate, 0.1% SDS and protease inhibitor cocktail and incubated on ice for  $\sim 30$  min. Cells were then sonicated for 100 cycles (30 s pulse, 30 s rest intervals) to an average size of  $\sim 500$ –800 bp using a 4 °C sonicator (Bioruptor UCD-200, Diagenode, Inc., Sparta, NJ, USA). After sonication, cell debris was pelleted by centrifuging 2 min, 4 °C at 8,000 g. Supernatant was collected and a 20  $\mu\text{l}$  input sample was analysed on a 2% agarose gel to verify chromatin size. Additionally, 100  $\mu\text{l}$  of recovered chromatin was used for DNA quantification and as qPCR positive control (Input). GammaBind Plus Sepharose Beads (GE Healthcare, Piscataway, NJ, USA; Cat. No. 17-0886-01) were blocked with BSA (100 ng  $\mu\text{l}^{-1}$  beads; New England Biolabs, Ipswich, MA, USA) and salmon sperm DNA (100 ng  $\mu\text{l}^{-1}$  beads; Invitrogen) for 30 min at RT. Beads were washed three times with RIPA buffer (50 mM Tris-Cl, pH 8, 150 mM NaCl, 2 mM EDTA, pH 8, 1% NP-40, 0.5% sodium deoxycholate, 0.1% SDS with protease inhibitor cocktail) and resuspended in two volumes of RIPA. Pre-clearing of recovered chromatin was performed by incubating with 100  $\mu\text{l}$  of blocked GammaBind Plus Sepharose Bead slurry for 30 min at 4 °C. Beads were centrifuged for 2 min, 4 °C at 8,000 g, and pre-cleared chromatin was recovered and further diluted 1:10 in RIPA for IP. IP was performed overnight at 4 °C by incubating  $\sim 50$   $\mu\text{g}$  of pre-cleared chromatin with 2  $\mu\text{g}$  of the following rabbit antibodies from Abcam: anti-Snf2h; anti-Snf2l; anti-histone H3; or rabbit IgG (Jackson ImmunoResearch). We also used anti-H3K9Ac; and anti-H3K9Me3 as internal controls. Immune complexes were captured with 120  $\mu\text{l}$  of blocked GammaBind Plus Sepharose Bead slurry for 2 h at 4 °C. Beads were then collected by centrifuging for 2 min at 8,000 g. Beads were washed three times with 20 mM Tris-Cl, pH 8, 150 mM NaCl, 0.1% SDS, 1% Triton X-100 and 2 mM EDTA, pH 8, and once with 20 mM Tris-Cl, pH 8, 500 mM NaCl, 0.1% SDS, 1% Triton X-100 and 2 mM EDTA (pH 8). DNA was eluted with 150  $\mu\text{l}$  of elution buffer (1% SDS, 100 mM NaHCO<sub>3</sub>) for 15 min at RT. Eluted DNA was further diluted in two volumes of elution buffer and incubated overnight at 65 °C with 100  $\mu\text{g}$  of proteinase K (Invitrogen) for crosslink reversal. The DNA was phenol-chloroform-extracted and resuspended in 100  $\mu\text{l}$  of TE, pH 8 (10 mM Tris-Cl, pH 8, 1 mM EDTA, pH 8). In all, 1  $\mu\text{l}$  (1/100th) of DNA was used per reaction for quantitative PCR analysis. Triplicate or quadruplicate samples were ran per reaction and three independent ChIP experiments were carried out per time point. Primers are listed in Supplementary Table 1.

**Quantitative real-time PCR.** For qPCR analysis of ChIP DNA, PCRs were carried out using the SYBR Green Advantage qPCR premix (Clontech) and run under the following conditions: one cycle at 95 °C for 1 min, 45 cycles at 95 °C for 10 s, 60 °C for 10 s and 72 °C for 20 s. All primers were analysed by melt curve analysis and agarose gel electrophoresis after qPCR amplification. Primers are listed in Supplementary Table 1. The  $\Delta\Delta\text{Ct}$  method was used to compare fold-change. L32 was used as internal control. Triplicate or quadruplicate samples were ran per reaction and a minimum of three mice were analysed per genotype. Student's *t*-test was used for statistical significance.

**Reverse transcription.** Cerebella were quickly dissected from mutant and control littermates and RNA was isolated using Trizol (Invitrogen) according to the manufacturer's instructions. Glycogen (Ambion) was used as carrier. One microgram of total RNA was reverse-transcribed using random primers and SuperScriptIII (Invitrogen). cDNA was further diluted 1:20 and 1  $\mu\text{l}$  was used per qPCR (described above). RNA integrity is shown in Supplementary Fig. 9

**Microarrays.** Gene expression profiling was performed on RNA isolated from dissected cerebella tissue of P0 or P10 *Snf2h* cKO-Nes and wild-type control mice. RNA samples were labelled with Cy5 or Cy3 using 3DNA Array 900 kits (Genisphere, Hatfield, PA, USA) following the manufacturer's instructions. *Snf2h* cKO-Nes and control samples were then cohybridized to MEEBO 38.5K arrays (Microarrays Inc., Huntsville, AL, Canada). A total of four replicates were performed for P0 and three for P10 and in both cases the labelling dyes were flipped

for at least one replicate to counter dye bias. Probe-specific signals were quantified using the ScanArray express (Perkin Elmer, Waltham, MA). On the resulting raw background subtracted signals intra-array normalization (correcting for Cy5/Cy3 bias) was performed with global loess, inter-array normalization with the quantile method and statistical analysis via the WEBARRAY online tool (<http://www.webarraydb.org/webarray/index.html>).  $M$  ( $\log_2$  ratio of *Snf2h* cKO/control signal) and  $A$  values ( $\log_2$  average signal strength) were then determined for all probes. A probe (gene) was scored as differentially expressed on an array if it demonstrated a  $P$ -value  $< 0.01$ , and had sufficient detectable signals across all replicates ( $A$  value ( $\log_2$ )  $> 7$ ).

**Microarray filtering.** Cell-type-specific gene expression from P0 and P10 *Snf2h* cKO-Nes cerebellar arrays was determined by comparing the differentially expressed genes with the cell-type-specific gene expression lists from publicly available RNA-Seq data from adult cerebellar PCs, GCs and BG<sup>26</sup>. The unique gene identifiers of the differentially expressed genes from our arrays and from the RNA-Seq datasets were converted to MGI-approved gene symbols. This conversion ensures that genes presented with synonyms are not missed during the comparisons. The MGI symbols from the differentially expressed genes in our arrays were compared with each cell-type-specific gene list and reported as differentially expressed genes from *Snf2h* cKO-Nes cerebella in the corresponding cell types.

**Image acquisition and processing.** Tissue sections were examined and images captured using a Zeiss 510 laser scanning confocal microscope with UV (405 nm), argon (488 nm), helium/neon (546 nm) and helium/neon (633 nm) lasers. All images were acquired as 10–30  $\mu\text{m}$  Z-stacks (in 1–2  $\mu\text{m}$  intervals) and analysed as projections using the LSM 510 Image Browser software (Zeiss, Oberkochen, Germany). Epifluorescent and light microscopy images were acquired with a Zeiss Axiovert Observer Z1 epifluorescent/light microscope equipped with an AxioCam cooled-color camera (Zeiss). Images were exported to Adobe Photoshop CS5 (Adobe Systems Inc., San Jose, CA, USA) and further processed for contrast when necessary.

**Acid-based histone extraction.** Histones were acid-extracted from P2 and P9 *Snf2h* cKO and control cerebella or from Neuro2A cells after siRNA treatment. Briefly, cerebellar tissue was quickly dissected and separated from the inferior and superior colliculi and brain stem and snap-frozen on dry ice. Then, tissue was homogenized in TEB + buffer (0.1 M PBS, 0.5% Triton X-100, 5 mM sodium butyrate, 0.02% Na<sub>3</sub> complemented with protease inhibitors cocktail (Sigma)), lysed on ice for 20 min and centrifuged for 10 min at 2,000 r.p.m. at 4 °C. Then, the supernatant was discarded and the pellet resuspended in 0.2 N HCl at a cell density of  $4 \times 10^7$  cells per ml overnight with stirring at 4 °C. Samples were then centrifuged for 10 min at 2,000 r.p.m. at 4 °C and supernatant containing free histones collected and quantified for western blotting. The following antibodies were used from Active Motif: anti-histone H1 1:4,000 (no. 61201); anti-H2A acidic patch N-terminal 1:4,000 (no. 39111); anti-H2A C-terminal (no. 39591); anti-H2A T120ph 1:2,000 (no. 61195); anti-H2B 1:4,000 (no. 39125); anti-H2B K120Ac 1:4,000 (no. 39119); anti-macro-H2A1 1:1,000 (no. 39593). From Abcam: anti-H3 1:30,000 (no. 1791); anti-H4 1:5,000 (no. 10158); anti-H2AZ 1:5,000 (no. 4174); anti-H3K4Me3 1:10,000 (no. 8580); anti-H3K9Me3 1:5,000 (no. 8898) and anti-H3K18Ac 1:5,000 (no. 1191). From Millipore: anti-H3K36Me2 1:1,000 (no. 07-274); anti-pan-H3Ac 1:5,000 (no. 382158) and anti-H2A K119Ub1 1:200 (no. 8240; Cell Signaling). In all, 3–5  $\mu\text{g}$  of total histones were loaded onto 15% SDS-PAGE linear gels and immunoblotted as described above. All original western blots are shown in Supplementary Fig. 9. Colloidal Blue Staining Kit (Invitrogen) was used to assess histone stoichiometry in 18% SDS-PAGE linear gels as indicated by the manufacturer.

**Vector construction.** Human SNF2L cDNA comprising the entire open reading frame (+ exon1/– exon13/ + NLS) was amplified from a pcDNA3 expression plasmid<sup>64</sup> in a two-step process. The 5' end of SNF2L cDNA was amplified with SNF2L-EcoRI-Fwd (5'-TAAGGAATTCATGGAGCA-3') and SNF2L-XhoI-Rev-internal (5'-ACCTCTCGAGCTATGT-3') primers, followed by purification of the PCR products, restriction digest by EcoRI and XhoI, and directional subcloning into the pBRIT-LoxP-NTAP and pBRIT-LoxP-CTAP retroviral plasmid vectors, which have been previously described<sup>65</sup>. The remaining 3' sequence of SNF2L was then subcloned non-directionally following amplification with SNF2L-XhoI-Fwd-internal (5'-ATAGCTCGAGAGGTAG-3') and SNF2L-XhoI-Rev (5'-ATGCTCGAGGGATTCACCTTCTTG-3') primers and a restriction digest with XhoI. Similarly, SNF2H cDNA comprising the entire open reading frame was cloned into the pCI-neo expression vector (Promega Corp. Madison, WI, USA) then amplified with the SNF2H-BamHI-Fwd (5'-AAAAGGATCCATGTCGTC CGCGCCGAGCC-3') and SNF2H-XhoI-Rev (5'-AAAAGGATCCGAGTATGTCGTC TTCTTTTCTTCC-3') primers and directionally subcloned into the pBRIT-LoxP-NTAP and pBRIT-LoxP-CTAP vectors, following restriction digest with BamHI and XhoI. All clones were verified by sequencing at McGill University and Génome Québec Innovation Centre (Montreal, QC, Canada).

**siRNA knockdown on Neuro2A cells.** Neuro2A cells were freshly obtained from ATCC (Manassas, VA, USA) and grown in DMEM medium containing 10% FBS, l-glutamine and no antibiotics. Briefly, cells were grown to a confluency of ~80% and transfected using Lipofectamine 2000 (Invitrogen) with 75 nM siSnf2h (Thermo Scientific, Ottawa, ON, Canada; siGENOME, mouse *Smarca5*, D-041484-03); 75 nM siScrambled (siGENOME non-targeting siRNA no. 1, D-001210-01-05); or 75 nM siSnf2l (OriGene Technologies, Inc, Rockville, MD, USA; *Smarca1* (mouse) no. SR421862B). Total proteins or acid-extracted histones were collected as described above and analysed by immunoblotting.

**Fluorescence recovery after photobleaching.** Neuro2A cells were grown in DMEM medium containing 10% FBS, L-glutamine and  $1 \times$  penicillin/streptomycin. H1e-GFP plasmid has been previously described<sup>34</sup>. FRAP experiments were conducted essentially as described<sup>33</sup>. Cells were grown in eight-well  $\mu$ -slides (ibidi LLC, Martinsried, Germany) and transfected with H1e-GFP plasmid together with 75 nM of each of the siRNAs using Lipofectamine 2000 (Invitrogen). For hSNF2H and hSNF2L 'addback' studies, pBRIT-FLAG-hSNF2H or pBRIT-FLAG-hSNF2L was added to the transfection mix. Photobleaching studies were performed using a Revolution spinning disk (CSUX, Yokogawa, Japan) and an EMCCD high-speed imaging system (Andor Technology, Belfast, UK) equipped with a FRAPPA module (Andor Technology) and with solid-state lasers mounted on an Olympus IX81 fully automated microscope. During the entire imaging process, cells were maintained under controlled CO<sub>2</sub>, temperature and humidity using an environmental chamber (Life Imaging Services, Basel, Switzerland). Bleaching was performed with a  $\times 60$  oil objective (NA = 1.4). Images were captured every 250 ms using an EMCCD iXon + camera (Andor, UK). Typically 240 post-bleach images were collected. Data from more than 20 cells were collected per experiment. All FRAP experiments were performed at least three times and plots for one representative experiment are shown. Data processing was performed using the easyFRAP program<sup>66</sup>, based on the double normalization method<sup>67</sup>. Curve fitting was performed using MATLAB's non-linear least-squares function. The method to calculate fully normalized recovery curves has been described previously<sup>68</sup>. This method was used to estimate the mobile protein fraction and t-half of protein. Two-tailed Student's  $t$ -test was used to compare the significance of differences between FRAP curves<sup>69</sup>.

**Transmission electron microscopy.** Cerebella (E18.5, P7 and P21) were collected under a stereomicroscope, cut into sections of 1–2 mm thickness through the cerebellar vermis region and fixed for at least 4 h to overnight in Karnovsky's fixative (4% PFA, 2% glutaraldehyde and 0.1 M cacodylate in phosphate-buffered saline, pH 7.4) at 4 °C. These specimens were subsequently washed twice in 0.1 M cacodylate buffer for 1 h and once overnight at RT. Sections were then post-fixed with 1% osmium tetroxide in 0.1 M cacodylate buffer for 1 h at 4 °C, and washed twice for 5 min in water. The specimens were dehydrated twice for 20 min for each step in a graded series of ethanol from water through 30–50–70–85–95% ethanol and twice for 30 min in 100% ethanol (molecular sieves were used to dehydrate ethanol), followed by twice for 15 min in 50% ethanol/50% acetone and twice for 15 min in 100% acetone. Sections were infiltrated in 30% spurr/acetone for 15 h (overnight) then in 50% spurr/acetone for 6 h and in fresh 100% spurr resin overnight. Spurr was changed twice a day for 3 days at RT. All infiltration steps were carried out on a rotator. Sections were then embedded in fresh liquid spurr epoxy resin and polymerized overnight at 70 °C. Ultrathin sections (80 nm) from the cerebellar vermis were collected onto 200-mesh copper grids and allowed to dry overnight before staining. Grids were stained with 2% aqueous uranyl acetate and with Reynold's lead citrate. Sections were observed under a transmission electron microscope (Hitachi 7100). All ultrastructural analyses were based on at least three mice per genotype of the same age for each group examined.

**Toluidine blue staining.** Semithin sections of 0.5  $\mu\text{m}$  were stained with 1% toluidine blue and 2% borate in distilled water. Histological samples were scanned with a MIRAX MIDI automated scanning light microscope (Zeiss) and images processed with Zeiss MIRAX Viewer software (Zeiss).

**Statistics.** Group statistical analysis was performed via two-tailed Student's  $t$ -test or one-way ANOVA, where indicated.  $P < 0.05$  was accepted as statistically significant. At least three mice per genotype were used for evaluation. Values are presented as the mean  $\pm$  s.e.m.

### Acknowledgements

We are grateful to Dr Diane Lagace and Mirela Hasu at the University of Ottawa Behavioral Core for assistance with behavioural experiments and expert discussions. We thank Dr Alexandra Joyner for pan-Engrailed antibodies. M.A.-S. thanks D.J.P. for funding and Dr Peter Becker for expert discussions. This work was funded by operating grants GACR P305/12/1033 and UNCE 20421 to T.S.; NIH grant R01 CA079057 to A.I.S.; and CIHR grants MOP97764 and MOP84412 to D.J.P.

### Author contributions

M.A.-S. designed, interpreted and executed all experiments. D.J.P. supervised the project. K.Y., E.H., D.I., M.S.H. and M.A.T. provided technical support. P.S.L. and C.P.C. helped establish the breeding colony and made some preliminary phenotypic observations with the *Snf2h* cKO-Nes mice. Y.D.R. and R.K. performed and analysed TEM experiments.

E.V.R.R. and E.M. performed and analysed FRAP experiments. A.J.M., E.B., N.T. and V.A.W. performed and analysed *in situ* hybridizations and microarrays. D.Y. and I.I. provided bioinformatics support. *Snf2h<sup>fl/fl</sup>* and *Snf2h<sup>-/+</sup>* mice were generated and provided by T.S., J.K., R.M. and A.I.S. M.A.-S. and D.J.P. wrote the paper.

### Additional information

**Accession codes:** All raw and processed microarray data have been deposited into Gene Expression Omnibus under the accession number GSE42371.

Dear Matthew Todd,

Thank you for your request.

Permission is granted for you to use the material requested for your thesis/dissertation subject to the usual acknowledgements (author, title of material, title of book/journal, ourselves as publisher) and on the understanding that you will reapply for permission if you wish to distribute or publish your thesis/dissertation commercially.

You should also duplicate the copyright notice that appears in the Wiley publication in your use of the Material. Permission is granted solely for use in conjunction with the thesis, and the material may not be posted online separately.

Any third party material is expressly excluded from this permission. If any material appears within the article with credit to another source, authorisation from that source must be obtained.

Kind Regards

Emma Willcox  
Permissions Coordinator

#### PERMISSION/LICENSE IS GRANTED FOR YOUR ORDER AT NO CHARGE

This type of permission/license, instead of the standard Terms & Conditions, is sent to you because no fee is being charged for your order. Please note the following:

- Permission is granted for your request in both print and electronic formats, and translations.
- If figures and/or tables were requested, they may be adapted or used in part.
- Please print this page for your records and send a copy of it to your publisher/graduate school.
- Appropriate credit for the requested material should be given as follows: "Reprinted (adapted) with permission from (COMPLETE REFERENCE CITATION). Copyright (YEAR) American Chemical Society." Insert appropriate information in place of the capitalized words.
- One-time permission is granted only for the use specified in your request. No additional uses are granted (such as derivative works or other editions). For any other uses, please submit a new request.

# **APPENDIX F**

## **Curriculum Vitae**

## EDUCATION

- 2007- 2014**    **PhD Thesis (transfer from MSc), Biochemistry with specialization in Human Molecular Genetics, University of Ottawa ON, Canada**  
Thesis topic: Investigating the cellular role of PHF6, a gene implicated in intellectual disability and T-cell leukemia.  
Supervisor: Dr. David Picketts, Professor  
Funded by: NSERC Canada Postgraduate Scholarship, Ontario Graduate Scholarship, and an admission scholarship
- 2002-2007**    **BSc, Biopharmaceutical Science with specialization in Genomics, University of Ottawa, Ottawa, ON, Canada**

## ADDITIONAL RESEARCH AND WORK EXPERIENCE

- 2008-2014**    **Teaching assistant/lab demonstrator, University of Ottawa**  
Courses: Introduction to Biochemistry, Molecular Biology lab  
Supervisors: Dr. Vas Mezl, Dr. Gabriel Guillet, Dr. Luc Poitras
- 2006**            **Co-op Student, Research and Development, Sanofi Pasteur Canada Ltd, Toronto ON, Canada**  
Research project: Designing a capillary isoelectric focusing method to analyze vaccine components.  
Supervisor: Dr. Marina Kirkitadze, Senior Scientist
- 2005**            **Co-op Student, Medicinal Chemistry department, Merck Frosst Canada Ltd, Kirkland QC, Canada**  
Research project: Designing high throughput HPLC-MS/MS screens for the analysis of cytochrome P450-related drug-drug interactions.  
Co-supervisors: Dr. Qingping Wang and Jean-Francois Levesque  
Funded by: NSERC Undergraduate Student Research Award
- 2005**            **Co-op Student, Analytical Chemistry department, MethylGene Inc, Montreal QC, Canada**  
Research project: Developing an in-house HPLC-MS/MS method for analyzing drug inhibition with cytochrome P450 enzymes.  
Supervisor: Dr. Xuejun Peng
- 2004**            **Undergraduate Research Student, Chemistry department, University of Ottawa and the Biologics and Genetic Therapies Directorate, Health Canada, Ottawa ON, Canada**  
Research project: Developing a novel method for detecting histidine residues by MALDI-TOF  
Co-supervisors: Dr. Harvey Kaplan and Dr. Terry Cyr  
Funded by: NSERC Undergraduate Student Research Award

## AWARDS

<b>2011-12</b>	Ontario Graduate Scholarship
<b>2011-12</b>	University of Ottawa Admission Scholarship
<b>2011</b>	Institute of Human Development, Child and Youth Health Travel Research Award
<b>2007-09</b>	NSERC Canada Graduate Scholarship
<b>2007-09</b>	University of Ottawa Excellence Award
<b>2002-07</b>	University of Ottawa Undergraduate Admission Scholarship
<b>2002-07</b>	University of Ottawa Dean's Honour List
<b>2005</b>	NSERC Undergraduate Student Research Award
<b>2004</b>	NSERC Undergraduate Student Research Award
<b>2002</b>	Lena MacNeil Scholarship (declined)
